no significant comparisons. In contrast, the MA line shows a wide array of effects caused by crossing within the strain. When crossed with itself, the MA line shows higher survival at the York River site and reduced shell length at all sites except for Hungar's Creek in 2002. In 2003, pure strains of the MA line produced significantly higher survival at the Hungar's Creek site accompanied by reduced shell length at all sites. The NJ line shows no significant effects of inbreeding on any of our measurements at any of the sites in either year. Pure SC stocks were significantly larger in 2003 at the North River site, but there were no other differences. The VA line showed the most dramatic effects of crossing within-strain, with negative impacts at all sites where it was planted in both years except for survival in 2002 at the York River site and in 2003 at Wachapreague. All in all, the 2002 field data produced 10 significant pure versus hybrid contrasts out of a total of 46 possible tests, and of these 10, only 1 is positive indicating better survival of the MA pure strain relative to its hybrids lines at the York River site and 9 are negative indicating inferior growth or survival in the pure MA and VA lines at multiple sites. In 2003, however, of the 36 possible comparisons (owing to the destruction of the York River site), 2 show significant positive effects of within-line crossing (for survival of the MA line at the Hungar's Creek site and shell length of the SC line at the North River), and 7 are negative. Of these 7 all are in the MA and VA lines and 6 indicate inferior growth of pure crosses.

Comparing general combining abilities reveals strong differ-

ences in the pattern of significance among the parental lines (Table 3b). Groups with one KK parent are generally not significantly different from the average outbred strain at any site except for enhanced survival at the Quinby site in 2002 (Note, however, that this is the site where survival estimates are most suspect because of possible limitations of our sampling technique in the muddy substrate). Stocks with one MA parent survive in numbers equal to the average hybrid strain in both years, but are smaller at all sites in 2002 and at the North River site only in 2003. The NJ stock shows no significant general combining ability for any of the traits we measured. The SC parental stock shows no general combining ability for survival, but outbred strains with one SC parent are larger at all sites in both years. Stocks containing the VA parental line had lower than average survival until 2003 at the Quinby site and were smaller than the average outbred strain in both years with the exception of the Wachapreague site in 2003.

The midparent contrasts, evaluated separately at each site also show mixed effects (Table 3c). For survival until Autumn 2002, only 4 of the possible 42 contrasts are significant, with 2 being negative and 2 positive. In the autumn of 2003, of the 28 estimable contrasts only 1 shows a significantly positive nonadditive effect on survival. Many more of these contrasts are significant for shell length, with 15 of 42 significant in 2002, and 5 significant in 2003. In 2002 and 2003, all of the significant contrasts for shell length are positive, indicating that when these contrasts are significant, hybrid progeny are larger than expected from additive contribu-

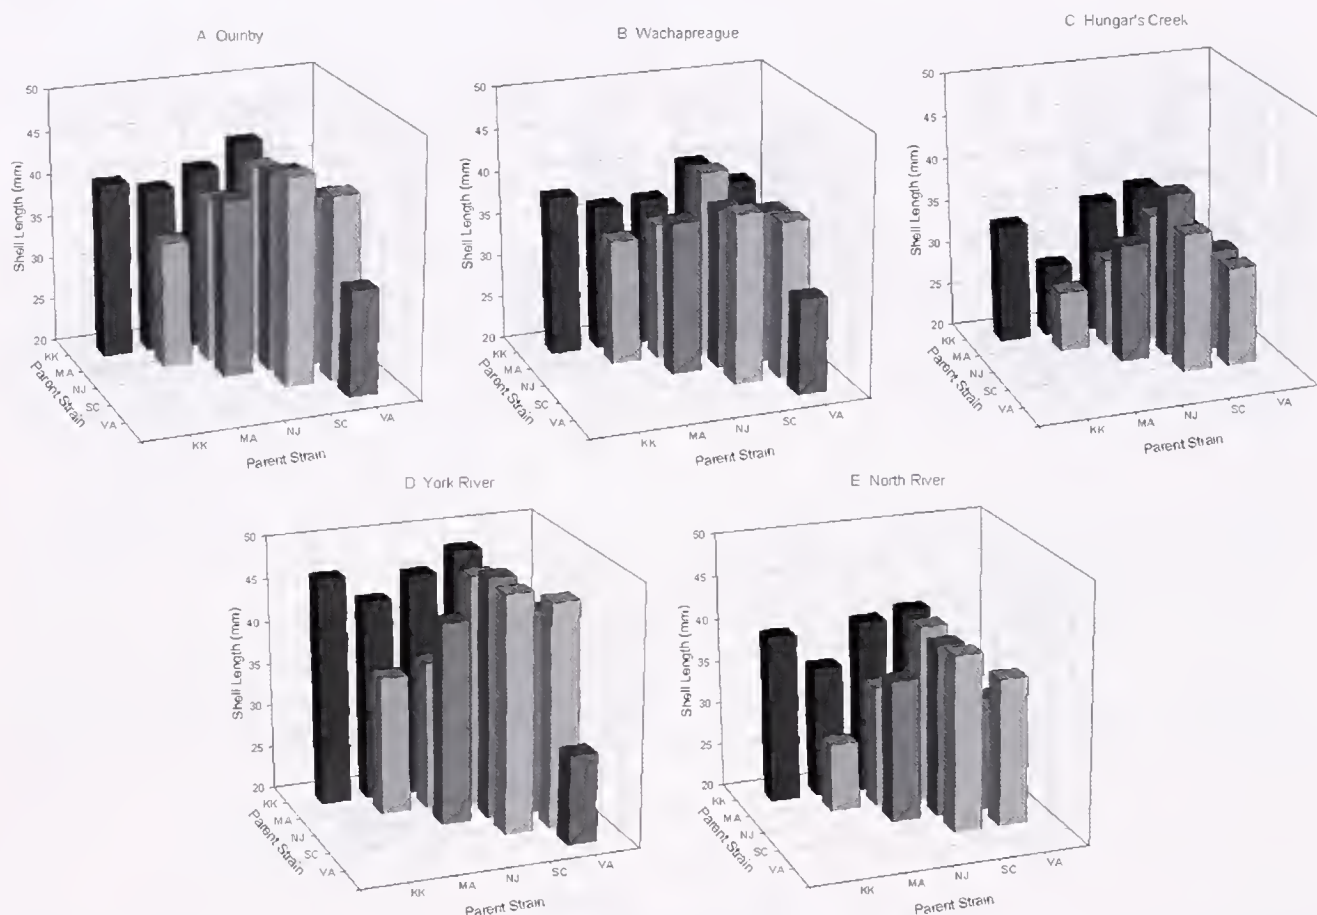

Figure 5. Shell length (largest dorso-ventral dimension) at the Fall 2002 sampling date of all possible combinations of the 5 parental stocks at each of the 5 field sites.

tions of parental strains. Further nearly all of the significant contrasts involve either the VA or MA parental lines as parents with the only exceptions being a significant positive effect on length for the NJ \times SC cross at the North River site in both years.

Table 4 shows the group-level among-site correlations for survival and shell length in both Autumn 2002 and Autumn 2003. The survival data (Table 4a) produced only one statistically significant correlation, a positive relationship between survival at the Wachapreague and York River sites in 2002 (note, however, that the York River site was destroyed before the 2003 sampling period). Shell length (Table 4b) is positively correlated among sites for all pairwise combinations of field sites in both years, with correlation coefficients ranging from 0.7–0.95.

Correlations Between Hatchery/Nursery and Field Measurements

Table 5 contains the correlation matrices among the group means of the two adult characters we measured and between juvenile and adult characters. The hatchery traits (spat area and seed length) are significantly correlated with each other ($r = 0.311$). The correlation between adult shell length and the number of survivors is significant in 2003 ($r = 0.223$), and at the Quinby site in both 2002 ($r = 0.525$) and 2003 ($r = 0.557$). There are, however, significant correlations between seed length, but not spat area, and both adult dimensions with correlation coefficients ranging from about 0.6 to nearly 0.9.

DISCUSSION

This study reveals a number of patterns that should be taken into account by both commercial clam growers and by breeders seeking to develop domesticated and genetically improved hard clam strains. In the field, it is no surprise that site selection has strong influences on the average survival of the genetic strains we produced in this study (Fig. 3 and Fig. 4) and weaker effects on growth (Fig. 5 and Fig. 6). Both clam culturists and breeders should place a high priority on survival, with growers seeking sites that maximize survival and breeders seeking to improve and to stabilize survival across a range of conditions. This is consistent with the finding that in Pacific oysters survival is more genetically variable than growth (Ernande et al. 2004). Less pronounced, but also important are the consistently higher growth of specific strains regardless of the site at which they are planted. Despite statistically significant group by site interactions in the overall analyses, all of the groups that had one parent from either the KK or SC parental strains tended to be larger at all of our test sites, and there were no negative among-site correlations for survival or size-at-age measurements (Table 4). The implications of this for breeders are that if our results can be generalized beyond the small number of strains tested here, it may not be necessary to develop specialty strains for different environments because the same strains performed best in all environments despite significant genotype-by-environment interactions.

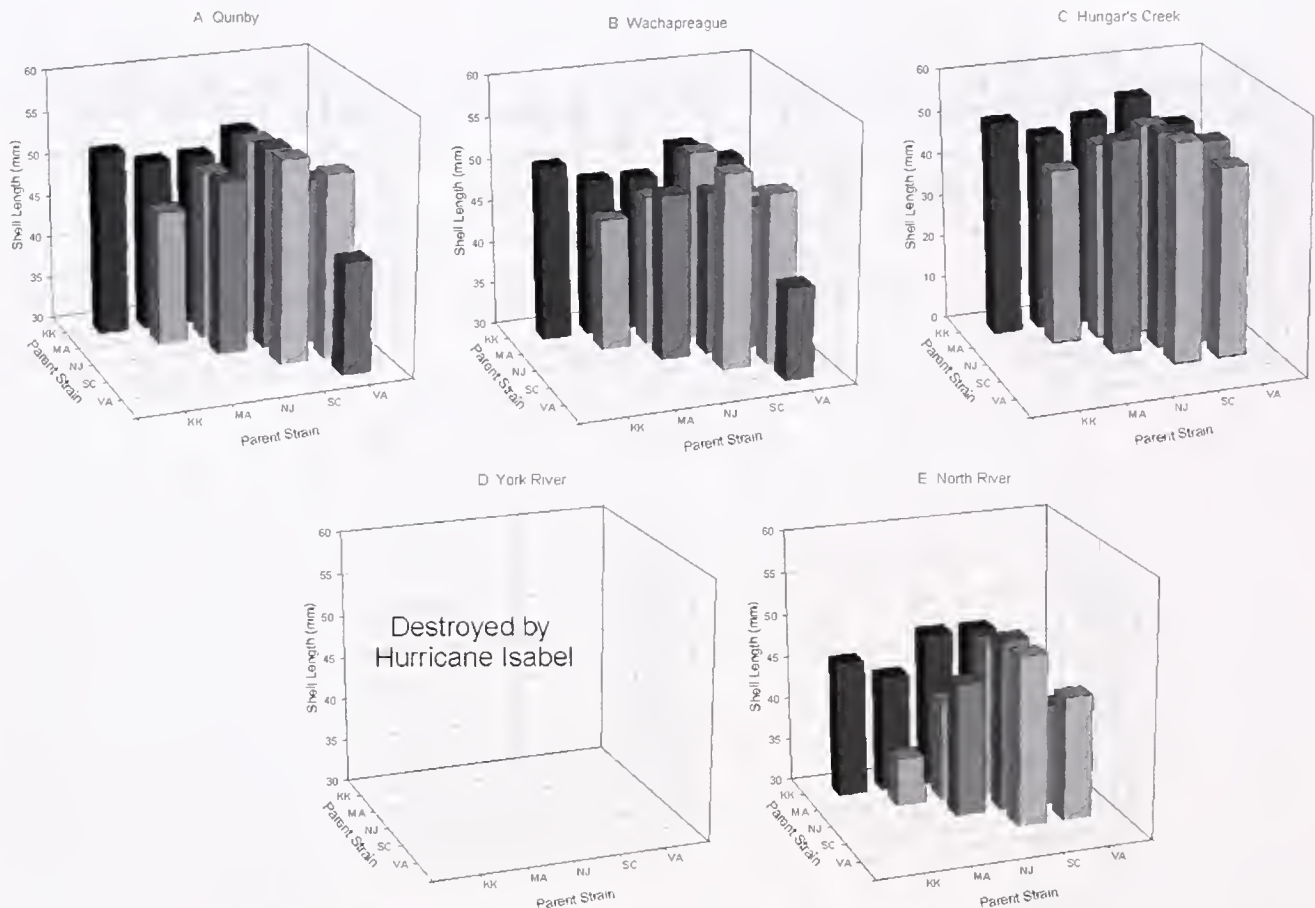

Figure 6. Shell length (largest dorso-ventral dimension) at the Fall 2003 sampling date of all possible combinations of the 5 parental stocks at each of the 5 field sites.

While we cannot be certain of the history of the stocks we used, all have been subjected to informal selection for a number of generations, and in some cases a combination of informal selection and inbreeding may have purged a substantial proportion of the deleterious alleles resulting in superior performing strains that can tolerate inbreeding. The implication here is that some low level of inbreeding may not be as detrimental as expected if it is accompanied by selection against deleterious alleles. The interplay between inbreeding and selection can be complex, especially in the presence of epistasis, genotype \times environment interaction, or genetic correlations. While there is still a great deal of both theoretical and empirical work required in this area (see Chap. 10 in Lynch & Walsh 2000), our data suggest that more precise studies of inbreeding and selection could be useful in designing an effective selective breeding program for hard clams.

In addition, breeders and broodstock managers must take into account their specific goals when making selection and management decisions. If, for example, the goal of a selective breeding program is to develop high-performance strains for use in aquaculture, our data indicate that some balanced between inbreeding and selection may purge deleterious alleles and produce high performing lines with little or no inbreeding depression. On the other hand, if the goal is to produce a genetically variable stock (e.g., for ecological restoration) then purging alleles that are deleterious under current conditions could have the undesirable effect of constraining the ability of restored populations to respond to changing conditions or novel pathogens.

Inbreeding effects also vary in the course of development. Crossing within strains, evaluated as the comparisons between pure and hybrid strains (Table 1b) generally has positive effects on spat area relative to among-strain crosses, with the exception of the VA stock, but negative effects later in development as measured by seed length. The same pattern is clear in the comparisons of hybrid lines to their midparent values (Table 1d), with hybrid progeny consistently smaller than the mean of the two parental lines as spat, but larger as seed. The most likely explanation for this pattern is that selection has been more intense and consistent for improved larval and nursery performance than for growth in the field under commercial conditions. All clam hatcheries experience high levels of larval mortality during the larval phase and aggressively sieve their larval cultures to eliminate dead and slow-growing larvae. In addition, the conditions in different hatcheries are likely to be quite similar because density, temperature, and food availability are relatively simple to control. In the field, however, mortality is typically lower and conditions are more variable from site to site. As a consequence, selection is likely to have been less intense and/or more variable in the field. Thus, selection in hatcheries is more likely to fix either favorable recessive genes or beneficial epistatic gene combinations and out-crossing is more likely to have detrimental impacts on hatchery performance.

In the field, the effects of crossing within parental strains are more complex. The significant comparisons between pure and hybrid groups that indicate negative effects that may be caused by inbreeding depression were concentrated in just two of the five

TABLE 3.

Parameter estimates and significance tests of linear contrasts: A. Contrasts of the mean of each "pure strain" to the mean of the four hybrid strains to which it contributed. B. Contrasts of the mean of the four "hybrid" groups that have the focal group as one parent to the mean of all ten hybrid groups. C. Contrasts between each outcrossed hybrid group and the mean of its two pure strain parental groups.

parent strains that we tested—the MA and VA lines, both of which also showed large negative effects for general combining ability. The few positive effects of crossing within strains occurred in lines that also showed better overall performance (KK and SC), indicated by positive general combining ability. Hence, at least in this first hybrid generation, there is an association between the ability of a line to raise the mean growth of any group to which it contributes genetically and the absence of negative effects of crossing within that line. Conversely lines with negative general combining ability for growth also show inbreeding depression as pure strains relative to hybrid lines.

Our data also provide evidence of nonadditive effects of out-crossing in some of our hybrid crosses. As for pure versus hybrid contrasts, midparent contrasts are significant mainly for crosses involving two of the five parental strains, MA and VA. Keeping in mind that these two lines also show the most severe negative impacts of within-line crossing, as indicated by the pure versus hybrid contrasts as well as negative effects in the general combining ability contrasts, the positive nonadditive effects of out-crossing for these strains are attributable less to the superiority of hybrids, than to the poor performance of these two pure lines. That is, whereas hybrid crosses involving the MA and VA line are likely to exceed expectations based on the mean of their parental lines, these crosses are still inferior to hybrid crosses among other parental strains.

Our analysis of midparent comparisons in the hatchery and in the field, however, cannot determine whether they are the result of

dominance or epistasis. Under the dominance hypothesis, hybrid crosses involving the poorest pure lines would perform better than the mean of their parental strains because of dominance of the alleles from the other (better) parent. Alternatively, to the degree to which the parental lines are homozygous at loci involved in epistatic complexes, this first generation of hybrid progeny would be expected to inherit entire gene complexes from their parents; and we would expect, therefore, that out-crossing of the poorest pure strains would also tend to enhance the performance of F_1 progeny by increasing the probability that they possess alleles that interact favorably. Only in the second generation posthybridization would we expect such fixed complexes, if they exist, to be disrupted by recombination (Falconer & Mackay 1996, Lynch & Walsh 1998). It is important, however to note that these nonadditive effects are restricted to the poorest performing parental lines and that there was little indication of nonadditive gene action in line crosses among the better parental lines. Thus, selective breeding and domestication efforts that emphasize selection on additive genetic variance should be effective, and our data provide no reason to believe that more complicated breeding schemes designed to use nonadditive heterotic effects, whatever the mechanism, would be advantageous over the judicious selection or construction of a base population with low inbreeding depression.

Further, the data presented here suggest that the beneficial effects of out-crossing we observed are not likely to be the result of heterozygosity *per se*. If that were the case, we would have expected that out-crossing would have improved performance in all

TABLE 5.

Pairwise correlation coefficients and significance tests among the group means of three adult characters (shell length, width and number of survivors), between these characters and two of the characters measured in the hatchery and nursery (shell length at the seed stage and the area of spat) and between the spat and seed measurements (this reported only once below the diagonal).

strains by increasing genome-wide heterozygosity. This is clearly not the case for most of the strains we tested. The two best-performing stocks (KK and SC) as well as the NJ strain show no advantages of outcrossing, and the two lines with the poorest performance show the strongest inbreeding depression.

Finally, there is evidence, at least at the level of strain-means we examined here, that growth performance in the field could be reasonably well predicted by measurements taken at an early stage in the culture process. Measurements collected on same-age spat when they were transferred from the upwelling system to nursery bags were essentially uncorrelated with size at the end of one or two growing seasons, a result that agrees with the findings of Hilbish et al. (1993) who found no significant genetic correlation between early larval growth (0–10 days) and shell length at 9 mo of age. However, the significant correlation between the shell length of seed when it was removed from the spat bags and planted into the field plots and adult characters indicate that seed size at a specific age may be a useful predictor of subsequent growth. This implies that the identification of superior seed for planting in the field could potentially be accomplished based on measurements taken under nursery conditions in commercial farms. Also, in the context of a selective breeding effort, it may be possible to identify and cull the most inferior genotypes based on measurements of juveniles, eliminating a great deal of the labor required to rear all of the animals being tested to harvestable size for evaluation.

Further study is required. Especially interesting would be an assessment of the levels of allelic richness and heterozygosity of both the parents and the progeny and an evaluation of whether these change over time as a consequence of selective mortality of more homozygous progeny. In addition, studies of more advanced

hybrid generations are necessary to identify the genetic mechanisms underlying the phenotypic effects we detected.

ABSTRACT An individual-based model was developed to simulate growth of the hard clam, *Mercenaria mercenaria*, in response to temperature, salinity and food supply conditions. Unique characteristics of the model are that: (1) length and tissue weight are related only by condition index, so that weight, up to a point, can vary independently of length, and (2) age is decoupled from length. Tissue weight changes result from the difference in assimilation and respiration. Changes in hard clam condition are determined from a standard length-weight relationship for average hard clam growth. Changes in hard clam length (growth) occur only when condition index is greater than zero, which happens when excess weight for a given length is attained. No change in length occurs if condition index is zero (mean case) or negative (less weight than expected at a given length). This model structure resolves limitations that accompany models used to simulate the growth and development of shellfish populations. The length-frequency distribution for a cohort was developed from the individual-based model through simulation of a suite of genotypes with varying physiological capabilities. Hard clam populations were then formed by the yearly concatenation of cohorts with partially independent trajectories that are produced by cohort- and population-based processes. Development and verification of the hard clam model was done using long-term data sets from Great South Bay, New York that have been collected by the Town of Islip, New York. The ability to separately track length and age in the simulations allowed derivation of a general mathematical relationship for describing age-length relationships in hard clam populations. The mathematical relationship, which is based on a twisted bivariate Gaussian distribution, reproduces the features of age-length distributions observed for hard clam populations. The parameters obtained from fitting the twisted bivariate Gaussian to simulated hard clam length-frequency distributions obtained for varying conditions yield insight into the growth and mortality processes and population-dependent processes, compensatory and otherwise, that structured the population. This in turn provides a basis for development of theoretical models of population age-length compositions. The twisted bivariate Gaussian also offers the possibility of rapidly and inexpensively developing age-length keys, used to convert length-based data to age-based data, by permitting a relatively few known age-length pairs to be expanded into the full age- and length-frequency structure of the population.

INTRODUCTION

Hard clam (*Mercenaria mercenaria*) populations in the bays along the south shore of Long Island, New York, have diminished since reaching peak abundance in the 1970s (Schlenk 2000). The definitive cause of this decline has not been demonstrated, but intensive harvesting may have initially reduced clam abundance (Buckner 1984, COSMA 1985) and experimental observations suggest that recent occurrences of the toxic picoplanktonic alga *Aureococcus anophagefferens* (brown tide, Pelagophyceae) may have impacted larval and juvenile survivorship (Bricelj 2000). Hard clam growth rates may have declined relative to past years (Cerrato 2000a), and the same factors slowing growth may have led to decreased gamete production.

During the 1990s other biological and environmental factors, such as temperature, salinity, phytoplankton species and/or concentrations, and predator abundance, may have changed as well. For example, during the 1990s, mean winter water temperature in the Long Island region was 1°C to 3°C warmer than the long-term average (Nixon et al. 2004). A significant predator, the blue crab

(*Callinectes sapidus*), may have recently increased its population levels in this region. Hard clam abundance may have declined enough to adversely affect fecundity (Kraeuter et al. 2005). Thus, the observed reduction in hard clam abundance and the failure of the Great South Bay fishery to recover, despite a reduction in fishing pressure in recent years, likely result from multiple factors.

A mathematical model provides one approach for investigating the relative effect of the many potential factors affecting hard clam populations. The first objective of this study is then to develop a mathematical model that can simulate the growth and population dynamics of the hard clam in response to specified biological and environmental conditions. The model is implemented for Great South Bay, NY where long-term data sets on hard clam abundance and distribution, collected by the Town of Islip, NY, provide calibration and evaluation of the simulations.

An additional important consideration for the Great South Bay ecosystem is development of management strategies that allow rebuilding of the now depleted hard clam stocks. A reliable means for determining population age-length characteristics is an important aspect of developing management strategies because fisheries models, such as virtual population analysis models, depend on age-frequency information for the population (e.g., Hilborn & Walters 1992, Patterson 1998, Clark 1999, Bradbury & Tagart

*Corresponding author. E-mail: hofmann@ccpo.odu.edu

2000). The age structure of populations is also important in ecological research, as indicated by the many theoretical and empirical studies that relate age and lifespan to population processes (e.g., Bayne et al. 1983, Hoenig 1983, Connell & Sousa 1983, Bayne et al. 1983, McNamara 1993, Lundberg & Persson 1993, Nunney & Elam 1994).

Population age is usually obtained from an age-length relationship that prescribes the likelihood that an individual of a given length will have a given age, the age-frequency at length, and conversely, the likelihood that an individual of a given age will have a given length, the length-frequency at age (e.g., Kimura 1977, Mohn 2001). For molluscs, aging typically relies on counting of yearly growth bands in shells (e.g., Cerrato 2000b, Goodwin et al. 2001, Richardson 2001) or statoliths (e.g., Lipinski et al. 1998, Richardson 2001). These methods are costly, time consuming, and technically difficult. As a consequence, most empirical studies do not measure the age distribution of all animals sampled from a population or compare age structures in multiple populations. This limits ecological research into the age-length structure of natural populations and the use of sophisticated age-dependent models in fisheries management.

Because of measurement limitations, information on age structure for multiple samples or assemblages typically relies on an age-length key to estimate age frequency from length frequency. Age-length keys can be as simple as mean age-mean length relationships for an individual cohort, normally obtained by fitting a growth model to empirical data (e.g., Tanabe 1988, Smith et al. 1997, Devillers et al. 1998, Millstein & O'Clair 2001). Many factors affect the length frequency of a single cohort over time (e.g., Craig & Oertel 1966). As a result, the age structure of a population derived from many cohorts may not necessarily match that of a single cohort or even a subset of cohorts and the population age and length structure determined using a cohort-based age-length key may not reflect the population as a whole.

Thus, a second goal of this study is to use the hard clam model, which simulates independently the age and length structure of the population, to investigate the age-length characteristics of a population that are produced by variations in environmental and biological processes. These simulations were used to derive a general mathematical function that describes the age-length relationship and its variations in hard clam populations. A general age-length relationship for hard clam populations provides an approach for inferring the processes that produced the population structure.

The hard clam population dynamics model is described in the next section. This is followed by an examination of simulations of hard clam growth and development for a range of environmental conditions and biological processes. Following this, the simulations that provide the basis for derivation of a hard clam age-length relationship are described and the mathematical formulation of the age-length relationship is given. The discussion section summarizes the results within the context of current understanding of hard clam populations.

MODEL DESCRIPTION

Hard Clam Model Structure

The hard clam model simulates a single individual with a particular physiology. The model structure is based on the assumption that changes in weight and length of an individual hard clam are related to the condition of the animal. This assumption is implemented by independently calculating hard clam weight and length over time. The weight obtained at any given time is compared with

an average length-weight relationship that was derived for hard clams (described below). The difference between the simulated weight and that obtained from the average curve determines how "fit" the hard clam is at a given time. The length-weight-condition coordinate system allows shell growth to be defined as a function of animal condition rather than as a function of animal weight. Changes in condition dictate whether length can increase. Positive condition supports somatic or reproductive tissue growth and normally shell elongation. Neutral or negative condition does not. This approach ensures that hard clam weight and length remain only partially coupled during a simulation because weight can change without requiring a corresponding change in length. As a result, realistic length-weight combinations cannot be exceeded, but reductions in condition can occur seasonally, as is observed.

Changes in hard clam weight, condition and length are produced by the environmental and physiological processes that control the growth and reproduction of an individual animal (Fig. 1). Ambient temperature, salinity, and total concentration of suspended solids modify filtration rate, which determines food ingestion. Assimilation is determined by the assimilation efficiency and loss to respiration. The apportionment of the resulting net production into somatic and reproductive tissue is determined by temperature, hard clam weight and animal condition. Somatic tissue growth during times of positive clam condition results in an increase in hard clam shell length. Reproductive tissue is formed when net production and condition are positive and temperature is favorable for reproduction. Spawning occurs when the gamete fraction exceeds a threshold fraction of total animal weight. Periods of negative net production result in resorption of reproductive tissue to cover metabolic needs and eventually resorption of somatic tissue.

A cohort is created from the individual-based model by a set of independently-simulated individuals defined by a range of physiological and genetic capabilities (Fig. 2). The frequency of each

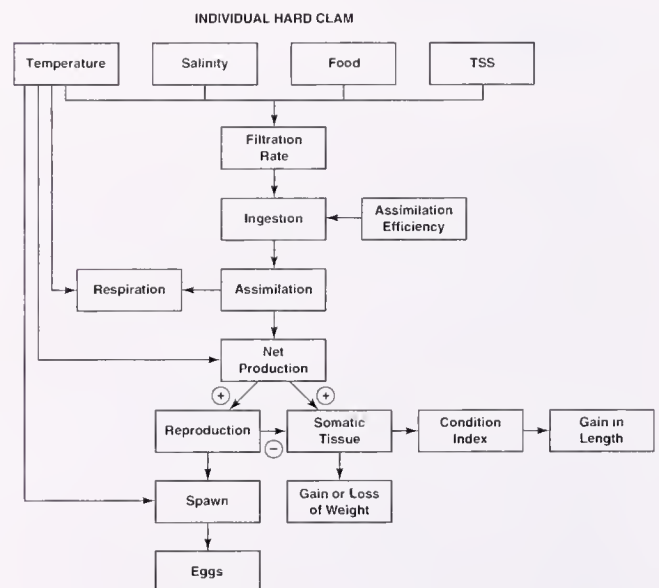

Figure 1. Schematic of the processes and transfers included in the individual-based hard clam model. Total suspended solids is abbreviated as TSS. The division of net production is determined by temperature, animal weight, and animal condition. Positive net production (+) results in formation of reproductive and somatic tissue. Negative net production (−) results in resorption of reproductive tissue.

Figure 2. Schematic of the approach used to scale the results of the individual-based clam model to the cohort and population level. For the Great South Bay, NY reference simulation (Figures 10 and 11), characteristics 1 and 2 were the length of a 2-y-old hard clam and assimilation efficiency, respectively. See text for details.

genotype in the cohort is determined by a probability distribution, described below, so that the cohort is a weighted sum of the set of independently-simulated individual genotypes. Concatenations of cohorts over a period of years, as determined by a broodstock-recruitment relationship, builds a hard clam population much as a series of yearly recruitment events and subsequent growth does in the natural world (Fig. 2).

The governing equations used to calculate changes in hard clam weight, condition, and length are described in the following section. This is followed by descriptions of the parameterizations used to represent the physiological processes determining growth and reproduction of an individual hard clam. The final sections describe the approaches used to specify the cohort and population genetics and the broodstock-recruitment relationship used to form the population structure.

Hard Clam Model Governing Equations

Weight Equation

Changes in hard clam body weight (W , mg dry wt) over time (t) are based on net production, which is given by the difference in assimilation (A) and respiration (R) as:

$$\frac{dW}{dt} = (A - R) W \quad (1)$$

The weight change obtained from Eq. (1) is the primary input into the calculation of hard clam condition index, described in the next section. The parameterizations for assimilation and respiration for the individual-based hard clam model are described in subsequent sections and definitions and values of coefficients are given in Table 1.

Condition Index Equation

Hard clam condition index, $C(L, W)$, is defined as a ratio of the current weight, $W(t)$ obtained from Eq. (1), to a standard weight, $W_0(L)$, and a maximum weight, $W_m(L)$, of an individual hard clam as:

$$C(L, W) = \frac{W(t) - W_0(L)}{W_m(L) - W_0(L)} \quad (2)$$

where the standard and maximum clam weights are functions of clam length, L (mm). The condition index obtained from Eq. (2) indicates how fit a clam is at any given time for a specified set of environmental conditions. Positive condition index, when a clam has a mass for a given length that is above the standard value, ranges from 0–1. Values less than zero occur when a clam has a mass for a given length below that obtained from the standard length-weight relationship.

The standard and maximum weights for individual hard clams as a function of clam length used in Eq. (2) are obtained from empirically-derived relationships. The weight and length observations for 30–120 mm hard clams given in Hibbert (1977) were used to develop an allometric equation. However, using this allometric equation for the standard length-weight relationship resulted in growth for 5–20 mm hard clams that was too rapid relative to observed growth rates for this size range. Examination of additional hard clam length and weight data (Krauter unpubl. data), that included 5–20 mm clams ($n = 450$), showed that small hard clams weigh more at a given length than is estimated from the Hibbert (1977) length-weight relationship. Combining the 5–20 mm hard clam data with the Hibbert (1977) data allowed a new average length-weight relationship to be obtained:

$$W_0(L) = a_0 L^3 + b_0 L^2 + c_0 L + d_0. \quad (3)$$

The maximum weight attained for a given length is:

$$W_m(L) = a_m L^3 + b_m L^2 + c_m L + d_m. \quad (4)$$

This length-weight relationship (Fig. 3) allows for small hard clams that are heavier for a given length and large clams that are longer for a given weight than the values obtained from the relationship derived by Hibbert (1977). The implication is that small hard clams do not follow allometric growth. Implementing Eqs. (3) and (4) with the hard clam model resulted in simulated growth rates that gave lengths during the first five years of clam life that matched the hard clam age-length observations given in Wallace (1991).

The time-dependent variation in hard clam condition index (Eq. 2) is calculated from changes in weight (Eq. 1), the average and maximum length-weight relationships (Eqs. 3 and 4, respectively) and length (Eq. 6 in the next section) as:

$$\frac{dC(L, W)}{dt} = \frac{1}{(W_m(L) - W_0(L))^2} \left[(W_m(L) - W_0(L)) \left(\frac{dW}{dt} - \frac{dW_0}{dL} \frac{dL}{dt} \right) - (W(t) - W_0(L)) \left(\frac{dW_m}{dL} - \frac{dW_0}{dL} \right) \frac{dL}{dt} \right]. \quad (5)$$

Length Equation

When excess weight for a given length relative to the average length-weight relationship (Eq. 3) occurs, a positive condition index, the excess weight produces an increase in shell length calculated as:

$$\frac{dL}{dt} = g(C) L \frac{L_{mf} - L}{L_{mf}} \quad (6)$$

where $g(C)$ is the rate of shell length increase and L_{mf} sets a maximum hard clam length. The form of Eq. (6) results in incrementally smaller increases in shell length as the maximum length is approached.

The rate of shell length change is a function of hard clam condition and is assumed to follow a hyperbolic relationship:

$$g(C) = g_{lmax} \frac{C(L, W)}{g_{lk} + C(L, W)} \quad (7)$$

where g_{lmax} is the maximum specific rate of increase in length, g_{lk} is the condition index value at which hard clam length increments at one-half the value of the maximum rate, and condition, $C(L, W)$, is obtained from Eq. (2). The rate of shell increase is analogous to the parameter in the von Bertalanffy equation, which determines the rate of length increase (k). As a result, observations and models

of hard clam growth (Kennish & Loveland 1980, Loesch & Haven 1973) can be used as a guide for determining the parameters controlling the rate of shell growth in Eq. (7).

Model Parameterizations

Filtration Rate

Doering and Oviatt (1986) provide a relationship for hard clam filtration rate (FR) as a function of clam length and temperature (T) of the form:

$$FR_0(L, T) = \frac{L^{fa} T^{fb}}{fc} \quad (8)$$

that allows filtration rate to increase with increasing hard clam length and temperature.

Results from experiments designed to show the effect of temperature on hard clam filtration rate over a range of lengths (Hamwi 1969) indicate that filtration rate is maximal between 17°C and 25°C, decreases at temperatures above and below these values, and ceases at 6°C and 32°C. This pattern holds over a range of hard clam lengths. This temperature dependency was incorporated by modifying Eq. (8) as:

$$FR_1(L, T) = FR_0 f_0 \left(1 + \tanh\left(\frac{T - T_{Low}}{T_f}\right) \right) \left(1 - \tanh\left(\frac{T - T_{High}}{T_f}\right) \right) \quad (9)$$

where the hyperbolic tangent function (\tanh) provides the temperature dependency that is observed in the observations presented in Hamwi (1969). However, the use of Eq. (9) with an upper temperature limit (T_{High}) on maximal filtration rate of 25°C produced incorrect growth rates for simulations that used summer temperatures that exceeded this value. Setting the upper temperature limit for maximum filtration rate to 29°C (Fig. 4) gave correct growth rates for hard clams in environments where the summer maximum temperatures exceeded 25°C. Some evidence for a higher temperature limit on filtration is provided by observations (Ansell 1968) that show hard clam growth up to 28–29°C, which then decreases at higher temperatures. These limited observations and the simulation results obtained using Eq. (9) suggest that a latitudinal variation in the upper temperature limit for hard clam maximum filtration may exist. However, verification studies using environmental conditions from southern regions have not been done. Thus, the form of the filtration rate temperature dependency for temperatures exceeding those typical of Great South Bay is tentative.

Figure 3. Standard hard clam length-weight relationship given by Eq. (3).

Additional experimental results show that hard clam filtration rate increases with increasing salinity (Hamwi 1969). This effect, described by a quadratic function, modifies filtration rate as:

$$FR_2(L, T, S) = FR_1(f_{s0} + f_{s1} S + f_{s2} S^2) \quad (10)$$

where S is the ambient salinity.

Increased total suspended solids (TSS , g dry wt L^{-1}) reduce the food acquired by hard clams through reduced filtration and increased pseudofeces production (Bricelj & Malouf 1984, Bricelj et al. 1984, Murphy 1985). The data given in Bricelj and Malouf (1984) and Bricelj et al. (1984) on the percent loss of algae in pseudofeces as a function of sediment concentration were used to develop a relationship that reduces the effectiveness of filtration with increasing TSS concentration. This effect is added to the filtration rate parameterization as:

$$FR(L, T, S, TSS) = FR_2(1 - a_{TSS} TSS^{b_{TSS}}). \quad (11)$$

The filtration rate given by Eq. (11) is the value that is input to the hard clam model.

Figure 4. Hard clam filtration rate as a function of temperature calculated using Eq. (9) for a 1 g dry wt clam.

Assimilation and Assimilation Efficiency

Assimilation (A) is determined by:

$$A = FR AE(W) Food(t) \quad (12)$$

where filtration rate (FR) is obtained from Eq. (11) and the weight-dependent assimilation efficiency, $AE(W)$, determines the fraction of the available food that is assimilated.

The assimilation efficiency consists of a base efficiency (AE_0) for clams less than 30 mm. The base assimilation efficiency is low (Table 1) because the filtration (Eq. 8) and respiration (see Eq. 14, later) relationships produce inordinately high growth rates for small hard clams. The low base assimilation efficiency compensates for this imbalance. The implication is that small hard clams have reduced assimilation, either because of lower filtration rates, less efficient filtration or lower assimilation efficiency because of shorter guts (Hughes 1980, Willows 1992). For larger hard clams, the assimilation efficiency increases in a hyperbolic manner with increasing weight as:

$$AE(W) = AE_0 + \frac{AE_1 W}{AE_k + W} \quad (13)$$

where AE_k is the weight (Eq. 3) of a 42.5 mm hard clam and the asymptotic assimilation efficiency is 0.80. The food time series ($Food(t)$) used in Eq. (12) is described in the Environmental Data Sets section.

Respiration

Respiration is the primary metabolic loss and is parameterized using a general bivalve relationship obtained at 20°C (Powell & Stanton 1985). This relationship was scaled for temperature effects on respiration by using the Q_{10} values for hard clam respiration that are summarized in Grizzle et al. (2000). These values were averaged, except for two that fell outside the range of the others, to obtain a Q_{10} value of 2.75. The respiration relationship is:

$$R(W, T) = a_r W^{b_r} e^{c_r(T-T_0)} \quad (14)$$

which gives increasing respiration rate with increasing temperature (Fig. 5). The respiration rate, in $\mu L O_2 h^{-1} clam^{-1}$, was converted to energy equivalent units using $4.75 \text{ cal } (mL O_2)^{-1}$, $5000 \text{ cal } (g \text{ dry wt})^{-1}$ (Hibbert 1977), and $4.184 \text{ cal } J^{-1}$.

Reproduction

Hard clams are assumed to be sexually mature when they reach 20 mm (Eversole 2000). For hard clams of this length and larger, positive net production is apportioned into somatic and reproductive tissue using a temperature-dependent reproduction efficiency of the form:

$$R_{eff}(T) = R_1 T - R_0 \quad (15)$$

Equation 15 applies over the range of temperatures, reported in Eversole (2000), at which hard clams form reproductive tissue. The temperature-dependent reproductive efficiency, which ranges between zero and 0.9, determines the fraction of net production that goes into reproductive tissue. The coincidence of positive reproductive efficiency and positive condition index, results in the formation of reproductive tissue. At high temperatures, reproductive tissue formation is limited by scope for growth, which is controlled by the rapid drop in filtration rate above 29°C (Eq. 9, Fig. 4) and by the number of days that hard clams experience temperature between 20°C and 27°C, as described in the following section.

Figure 5. Hard clam respiration rate as a function of temperature calculated using Eq. (14) for a 1 g dry wt clam.

Egg Production and Spawning

Spawning occurs when reproductive tissue is a certain fraction of total hard clam body weight and condition index is positive. These criteria, which set a spawning threshold, allow spawning to be dynamically determined by environmental conditions and hard clam condition, rather than being imposed.

The ratio of reproductive tissue to total body weight at which spawning occurs was determined by comparing the simulated number of eggs produced by a spawn to observations (Davis & Chanley 1956, Bricelj 1979, Bricelj & Malouf 1980, Malouf 1991, Eversole 2000) that show that an individual hard clam produces 20–40 million eggs in a year. Additional observations (Bricelj & Malouf 1980) show that the number of eggs produced drops as a function of hard clam weight as length exceeds 60–70 mm, which provides a constraint for simulated spawning.

The number of eggs produced in a simulated spawn was obtained by converting the reproductive tissue to eggs using 51 ng dry wt egg⁻¹ (Eversole 2000). The initial simulations that used a fixed ratio of reproductive tissue to total body weight to trigger spawns overestimated egg production per individual in comparison with observations. Moreover, in some simulations, large hard clams failed to spawn because the scope for growth was inadequate to reach the spawning threshold equivalent to that in the smaller clams. Thus, a spawn ratio (*SR*) that depends on hard clam weight of the form:

$$SR = SR_0 + (W - SR_1) SR_2 \quad (16)$$

was developed to provide the trigger for spawning. For hard clams less than 3 g dry wt, the ratio of reproductive tissue to total body weight at which spawning occurs is 0.2. As hard clam weight increases beyond 3 g dry wt, the spawn ratio decreases, reaching a minimum value of 0.08 for clams of 11 g dry wt. Spawning by larger hard clams is triggered at a lower fraction of reproductive tissue to total body weight, which reduces the number of eggs produced per gram weight for large hard clams (Fig. 6) because the total amount of gamete tissue spawned is smaller, but permits simulated total yearly egg production within the observed range (Eversole 2000).

Hard clams in Great South Bay spawn in June and July, with a small spawn in August (Kassner & Malouf 1982). Initial simula-

tions showed spawning that started at the correct time, but continued into September. The fall spawn resulted in total yearly egg production that was too high relative to observations (Eversole 2000). Observations indicate that spawning of Great South Bay hard clams ceases in the fall, although the processes that terminate spawning have not been identified. Attempts to end fall spawning at the appropriate time that were based on changes in food supply or temperature were unsuccessful. Thus, an *ad hoc* approach was developed that depends on days when the water temperature is between 20°C and 27°C, a temperature range that brackets the optimal range for hard clam spawning. Days with temperatures in this range add one quality day. Spawning occurs for quality days between 1 and 60; no spawn occurs if the cumulative quality days exceed 60. This terminates reproduction prior to the fall temperature decrease. The quality day approach resulted in simulated hard clam growth and reproduction that matched observations from Great South Bay. However, this quality day approach may not apply to lower latitude hard clam populations that are observed to spawn later into the fall.

Unspawned gametes are resorbed in the fall when the temperature declines. During times when the temperature is less than 12°C, the reproductive tissue that is stored as gametes (W_{reprod}) is used to support basic metabolic processes at a rate of 0.145 d⁻¹, which results in use of one-half of the gametic tissue in 4.5 days.

Genetic Variations and Development of Cohorts

Growth of individual hard clams varies in response to physiological characteristics and environmental conditions, which are reflected in the yearly cohorts that ultimately produce the population (Fig. 2). These variations come from the population genetic variability. For example, variations can arise from initial length, which determines an initial physiological state for an individual, and from differences in physiological responses, such as assimilation rate and respiration rate, which influence growth efficiency.

The genetically-determined variability ($GV_{i,j}$) of a cohort was obtained using a Gaussian function of the form:

$$GV_{i,j} = w_0 e^{-\frac{(C1_i - C1_0)^2}{2\sigma C1^2}} e^{-\frac{(C2_j - C2_0)^2}{2\sigma C2^2}} \quad (17)$$

Figure 6. Number of eggs produced as a function of hard clam weight calculated using Eq. (16).

TABLE 2.

Definitions, units, and values of parameters and coefficients used in calculations of the cohort and population structure.

Coefficient	Definition	Units	Value
w_0	initial clam density	ind m ⁻²	1
$C1_i$	characteristic 1 initial length variation	mm	specified
$C1_0$	characteristic 1 initial length	mm	26
σ_{C1}	characteristic 1 standard deviation	mm	6.0
$C2_j$	characteristic 2 assimilation rate variation	d ⁻¹	specified
$C2_0$	characteristic 2 assimilation efficiency mean value	d ⁻¹	1.0
σ_{C2}	characteristic 2 standard deviation	d ⁻¹	0.3
$imax$	maximum range characteristic 1	none	specified
$jmax$	maximum range characteristic 2	none	specified
Sz_0	smallest initial length	mm	12.0
Sz_n	largest initial length	mm	50.0
Mr_0	smallest assimilation efficiency value	d ⁻¹	0.25
Mr_n	largest assimilation efficiency value	d ⁻¹	1.75
Ra	broodstock-recruitment constant	ind g ⁻²	-3.26×10^{-3}
Rb	broodstock-recruitment constant	ind g ⁻¹	0.0863
Rc	broodstock-recruitment constant	ind m ⁻²	-0.00228
B_{DVO}	egg survival constant	(mg dry wt) ² g ⁻¹	-0.1192
A_{DVO}	egg survival constant	none	3.3119×10^{-8}
m_1	mortality rate constant	d ⁻¹	0.032
m_2	mortality rate constant	age ⁻¹	-1.5201
m_3	mortality rate constant	d ⁻¹	1.8916×10^{-4}
m_4	mortality rate constant	age ⁻¹	0.19016

where $C1$ and $C2$ represent the characteristics that are used to specify the genetic variability. The Gaussian distribution was centered about the mean value for each genetic characteristic and the range in variation for each was set by the standard deviation (σ_{C1} , σ_{C2}) about the mean value (Table 2). The range in variation associated with a particular characteristic is given by i and j . The Gaussian weight is normalized so that

$$\sum_{i=1}^{imax} \sum_{j=1}^{jmax} GV_{ij} = 1 \quad (18)$$

Equation 17 gives the cohort distribution of two characteristics. It can be expanded to include as many characteristics as are relevant to describing variations in the population.

The estimate of the range of variability in individual hard clams was obtained from data sets that give the range of lengths of hard clams for cohorts at age (Peterson et al. 1983, Grizzle 1988, Kennish unpublished data on 583 hard clams 0.5–10 y in age). These data were normalized by age and used to derive a relationship that relates the magnitude of the length range to age (Fig. 7). The normalized range suggests a two standard deviation variation in hard clam length at age. This was used as the basis to set the values of σ_{C1} and σ_{C2} in Eq. (17) to give a two standard deviation variation in particular clam characteristics about a mean characteristic value.

Equation 17 was implemented by allowing initial length, assimilation efficiency, and respiration rate to vary. Varying assimilation efficiency is equivalent to varying any process that affects assimilation, including filtration and ingestion rate. Variation in initial length (Sz) was introduced by:

$$Sz(i) = Sz_0 + 2(i-1) \text{ for } i = 1, Sz_n \quad (19)$$

where Sz_0 and Sz_n represent the smallest and maximum initial lengths, respectively. Variation in metabolic rates (Mr) was introduced by:

$$Mr(j) = Mr_0 + 0.05(j-1) \text{ for } j = 1, Mr_n \quad (20)$$

where Mr_0 and Mr_n represent the minimum and maximum range for a particular metabolic process. The initial and maximum values used for variation in length and assimilation efficiency are given in Table 2. Some combinations of initial length and metabolic rate will be less common in a given hard clam cohort and other combinations will be less viable overall either because of metabolic imbalances or metabolic inefficiencies. The surviving individuals

Figure 7. The magnitude of the length range for a hard clam cohort, standardized to cohort age, as a function of cohort age.

determine the genetic structure of the cohort. A cohort is produced in each year of the simulation and the yearly cohorts concatenated to produce the overall population structure (Fig. 2), as described in later sections.

Mortality

Simulations were started with 2-y-old hard clams because verification data from Town of Islip, NY stock assessments did not include quantitative counts of younger clams. The postsettlement mortality for the hard clams in the first and second years was absorbed into the recruitment calculation, which is described later. The mortality associated with the two-year and older postsettlement hard clam populations is assumed to be from natural processes, such as predation (Malinowski 1985). Mortality from starvation, temperature, and salinity are considered to be small in comparison and are not included as explicit losses. Combined mortality observations from field estimates and transplanted hard clams (Hibbert 1977, Kennish 1978, Buckner 1984, Walker 1983, Kraeuter unpubl. data) show that the specific mortality rate is higher for young clams, lessens for intermediate age clams, and increases for old clams. These data were used to develop daily specific mortality rates (M) as a function of hard clam age (CA) as:

$$M(CA) = m_1 e^{m_2 CA} \text{ for age } < 3 \quad (21)$$

and

$$M(CA) = m_3 e^{m_4 CA} \text{ for age } > 3 \quad (22)$$

where parameter definitions and values are given in Table 2. The daily specific mortality rates were then used to calculate the fraction of the population that survives (SF) to the next year as:

$$SF = 1 - M(CA) T_{yr} \quad (23)$$

where T_{yr} is the number of days in a year. The survival fraction obtained from Eq. (23) is highest for 2-to-4-y-old hard clams and decreases with age (Fig. 8).

Environmental Data Sets

Temperature and Salinity

Several time series of monthly temperature observations are available for Great South Bay. The year-long time series of monthly temperature observations for 1977–1978 (Bricelj 1979) was used for this study because of its completeness and because it appeared to best represent average conditions (Fig. 9A). The seasonal variation in temperature is as expected, with maximum temperatures in summer and minimum values in winter.

The limited available salinity data for Great South Bay (Quaglietta 1987) indicate that salinity variations are small, with maximum values occurring in late summer and fall. The observed salinity variation of Great South Bay is always near optimal levels for hard clams. These data were used to construct an idealized year-long salinity times series (Fig. 9B) in which salinity varies sinusoidally from a minimum of 22.5 to a maximum of 27.5 with the minimum occurring at year-day 100 (April 10).

Chlorophyll a and Food

Chlorophyll a concentrations for Great South Bay were measured during 1985 at weekly to monthly intervals, except for January, February and March (Quaglietta 1987). The three months for which data were not available were obtained by linear interpola-

Figure 8. Fraction of hard clams surviving as a function of clam age obtained from Eqs. 21–23. The change in slope of the curve at three years is produced by joining of the two mortality functions.

tion from the nearest measurements. The resultant chlorophyll a time series (Fig. 9C) shows low chlorophyll a from January to late April, after which concentrations about double as the spring bloom develops. Chlorophyll a values during the late summer are reduced from these maximum values and then increase again in late fall (Fig. 9C).

Figure 9. Time series of (A) temperature, (B) salinity, (C) chlorophyll a , and (D) food, calculated from chlorophyll a using Eq. (24), that were input to the individual-based hard clam model. The solid line on panel D indicates the time and duration of an imposed starvation period used for other simulations, as described in the text.

Chlorophyll *a* concentration (*chla*) was converted to food (Fig. 9D) using the relationship given in Soniat et al. (1984):

$$\text{Food}(t) = af + bf \text{chla}(t) \quad (24)$$

which includes a nonalgal food supply (*af*) that increases available food above that estimated from chlorophyll *a* and sets a lower limit on the food available to hard clams (Table 3). The importance of a nonalgal food source for marine bivalves has been established by independent measurements of protein, lipid, and labile carbohydrate in a number of bays and estuaries (Soniat & Ray 1985, Soniat et al. 1998, Hyun et al. 2001). The converted food time series (Fig. 9D) was input into the hard clam model via Eq. (12). The food time series resulted in simulated hard clam growth rates that match those reported in Wallace (1991).

Total Suspended Solids

A wide range in concentration of suspended solids (2–167 mg L⁻¹) has been reported for Great South Bay, with increased values associated with periods of high winds or runoff (Dennison et al. 1991). Monitoring activities during the summer of 1980 by Suffolk County, NY showed that suspended solids values usually are below 20 mg L⁻¹ (Dennison et al. 1991). Additional limited measurements of particulate organic matter for Great South Bay (Bricelj et al. 1984) and total seston for Long Island Sound (Evjen 1985) suggest an average concentration of 10 mg L⁻¹. Increases above this value occur in late fall and winter, which is at a time when clam filtration is reduced. The variation in summer values does not exceed this average value (Evjen 1985). Thus, the average total suspended solids concentration was used in the hard clam filtration relationship given by Eq. (11).

Hard Clam Model Implementation

Solution Method

The individual-based hard clam model consists of first-order ordinary differential equations that calculate the time-dependent rate of change of weight, length and condition. The dependence among these variables is such that only two are independent and the third can be obtained as a diagnostic calculation. In this implementation of the model, the change in condition and length are obtained from Eqs. (5) and (6), respectively, and are used to calculate weight from Eq. (1).

The set of differential equations is solved with a 5-stage, 4th-

order, compact storage Runge-Kutta solution scheme (Carpenter & Kennedy 1994). This solution procedure has truncation errors proportional to the time step to the fourth power making them accurate in time. The procedure has the further benefit of requiring that only two (instead of the more usual 4) intermediate solutions be saved.

Initial Conditions and Forcing

The individual-based model was initialized with a two-year-old clam using a range of sizes established by Eq. 19. As a result, simulation year 0 starts with a 2-y-old clam. Conversion of simulation year to actual clam age is done by adding two years. The hard clam simulations are run for 20 y with a time step of 1 day. The individual-based simulations were combined to form populations with one or more cohorts. A 20-y simulation is sufficient to develop a stable cohort and population structure.

The monthly-averaged environmental data sets input to the model were interpolated to daily values. The annual time series for each environmental variable (Fig. 9) is repeated in each year of the 20-y simulation. The simulated weight, length, and condition and additional diagnostic properties, such as egg production, are saved at 10-day intervals. Model calculations are done in terms of J (g dry wt)⁻¹.

Cohort and Population Calculations

A cohort is constructed from the individual-based model results and is composed of individual hard clams that recruit in the same year. The number of individuals m⁻² in a cohort at each combination of genetic variability (*N_{ij}*) is calculated as:

$$N_{ij} = N_0 GV_{ij} \quad (25)$$

where *N₀* is the initial number of individuals m⁻² in the cohort (Table 3) and *GV_{ij}* is calculated from Eq. (17). All of the cohort calculations used in this study started with an initial value of 1 ind m⁻², which is consistent with observed hard clam abundances in Great South Bay. The initial value is then apportioned among the various genetic combinations obtained by application of Eq. (17).

Age-dependent mortality, obtained from Eqs. (21, 22), is applied to the cohort and the annual survival fraction (Eq. 23) is used to calculate the reduction in total number of clams in a cohort in a given year as:

$$N_{ij}(\text{year}) = SF \times N_{ij}(\text{year}) \quad (26)$$

The total cohort biomass m⁻² (*CB*) is then obtained by summing the product of the number of hard clams associated with each genetic characteristic and the corresponding weight that each has in the month of June (*JW_{ij}*):

$$CB = \sum_{i=1}^{max} \sum_{j=1}^{max} N_{ij} \times JW_{ij} \quad (27)$$

The simulated June weight is used in the above calculation because this corresponds to the maximum (prespawn) weight for an individual hard clam.

The population biomass in a given year (*PB(year)*) is determined by summing across all cohorts

$$PB(\text{year}) = \sum_{k=1}^{Cmax} CB_k \quad (28)$$

where *k* represents the number of cohorts and *Cmax* is the maximum number of cohorts. The total population biomass obtained

TABLE 3.

Definitions, units, and values of parameters and coefficients used in implementation of the hard clam and the cohort and population calculations.

Coefficient	Definition	Units	Value
<i>a_f</i>	non-algal food concentration	mg dry wt L ⁻¹	0.520
<i>b_f</i>	food constant	(mg dry wt L ⁻¹) (μL L ⁻¹) ⁻¹	0.088

<i>bf₀</i>	cohort biomass reduction	none	6.3258 × 10 ⁻¹⁰
<i>bf₁</i>	cohort biomass reduction coefficient	(mg dry wt) ⁻¹	2.3659 × 10 ⁻¹¹

from Eq. (28) provides the spawning stock biomass that is used to calculate the number of surviving eggs (Eq. 30), as described below.

Population Recruitment

The number of eggs spawned provides the potential recruits that produce a cohort in a given year. Simulated egg production for the spawning stock cannot be converted simply into recruitment, however. A broodstock-recruitment relationship derived for Great South Bay hard clam populations suggests that survivorship varies nonlinearly as a function of broodstock biomass. This relationship was developed using data collected by the Town of Islip, NY, from 1978–2000 expressed as the number of 2-y-old clams in a given year as a function of broodstock biomass two years previously. This relationship is of the form:

$$R(\text{year}) = Ra \times PB(\text{year} - 2)^2 + Rb \times PB(\text{year} - 2) + Rc \quad (29)$$

where $R(\text{year})$ is the number of 2-y-old clams m^{-2} in a given year and $PB(\text{year} - 2)$ is the spawning stock biomass in g m^{-2} that existed two years previously. Kraeuter et al. (2005) provide additional information on the relationship between recruitment and broodstock in Great South Bay hard clam populations.

The relationship given by Eq. (29) results in a linear increase in recruits with increasing broodstock biomass up to a certain biomass, after which recruits level off as biomass increases, a process known as compensation. Compensatory processes involve cannibalism of young (e.g., Hunt et al. 1987) or competition for food among adults (Frechette & Lefavre 1990, Honkoop & Bayne 2002), which may reduce fecundity. A nonlinear dependency of spat density on spat survival, which may arise from variable predation rates over a range of clam densities (Peterson et al. 1995, Boulding & Hay 1984), would also produce a compensatory broodstock-recruitment pattern.

The broodstock-recruitment relationship given by Eq. (29) does not allow variations in recruitment in years when environmental conditions increase or restrict fecundity or survivorship for a given broodstock biomass. Therefore, the broodstock-recruitment relationship was used with an empirically-derived relationship between clam biomass and fecundity to determine egg survivorship. The biomass-fecundity relationship was obtained by first creating an average population length-frequency distribution from the Town of Islip hard clam data. Simulations using average environmental conditions for Great South Bay (described in the Environmental Data Sets section) were used to obtain hard clam egg production values for a wide range of hard clam lengths and weights. These egg-production values were prorated across the average length-frequency distribution to create a population average fecundity and the fecundity value was normalized to a broodstock value of $1 \text{ g dry wt m}^{-2}$. The 1-g dry wt m^{-2} value was then expanded across the range of anticipated population biomasses obtained from the broodstock-recruitment curve, with the assumption that the source of compensation in the biomass-recruitment curve is not adult competition for resources. In Great South Bay, average hard clam biomass does not normally exceed about 3 large clams m^{-2} and this density is unlikely to create conditions limiting clam ingestion, thereby producing competition for resources.

The clam biomass-fecundity relationship was used with the estimate of the number of two-year-old recruits obtained from the broodstock-recruitment curve for a given population biomass to obtain the average egg survivorship to a 2-y-old clam for a range

of population biomass levels. The resulting relationship describing the fraction of eggs surviving to become two-year-old clams (S_{2yo}) as a function of population biomass is of the form:

$$S_{2yo} = A_{2yo} e^{T_{2yo} PB(\text{year}-2)} \text{Eggs} \quad (30)$$

where parameter definitions and values are given in Table 2. Eq. (30) gives decreasing survivorship with increasing hard clam biomass, thus maintaining the general compensatory relationship defined by the broodstock recruitment curve, while also allowing conditions of inherently higher fecundity to result in inherently higher recruitment.

A hard clam population is constructed from the yearly cohorts. In each year, a new cohort enters the population with a number of individuals and size structure as described by Eq. (19) and (30). As a consequence, population age frequency and length frequency are independent characteristics, length being derived from the growth of each individual genotype in each cohort and age by the time of cohort birth.

RESULTS

Individual Hard Clam Simulations

Individual Hard Clam Reference Simulation—Basic Characteristics

The simulated length and weight change of an average individual hard clam (Fig. 10) followed the normal pattern, with increases in weight being larger for smaller-sized clams and length increases being greater for larger clams. Decreases in weight, such as the one that occurs at about 40 mm, result from spawning. For Great South Bay environmental conditions, the simulated length and weight remain above the standard curve, except when spawning occurs, and never exceed the maximum length and weight allowed for hard clams.

The simulated hard clam dry weight (Fig. 11A) increases during the first five simulation years, after which the rate of increase in dry weight declines and levels out at 4–5 g. The short-term decreases in weight are associated with spawning, which is most frequent in simulation years 2 and 3 (hard clam years 4 and 5). Short-term fluctuations in weight decrease in the later years of the

Figure 10. Simulated hard clam length and weight obtained from the reference simulation with the individual-based model. The standard and maximum hard clam length-weight curves obtained from Eqs. 3 and 4, respectively, are shown for comparison. Decreases in simulated hard clam weight at a given length are associated with spawning events or times of negative scope for growth.

simulation as the hard clam gets larger and older and spawns less frequently. The weight decrease that begins in winter and extends into the spring of each simulation year results from reduced food (Fig. 9D) during this time. The simulated change in hard clam length (Fig. 11A) is rapid in the first five simulation years, after which length increases slowly to a maximum value of about 79 mm. The periods of constant length in each simulation year coincide with periods of weight loss, such as occurs during the winter and spring.

The reference simulation is for a hard clam with an average genotype for the cohort as defined by Eqs. (19) and (20). As a consequence, some members of the cohort will grow slower and others faster than this average animal. Likewise, some spawn more and others less frequently. This is then a representative hard clam genotype for the cohort, but not the only genotype. The simulated condition index (Fig. 11B) of this average hard clam ranges between 0.4 and -0.4. Positive condition corresponds to times of increase in weight and shell length and occur mostly during the

first five simulation years. Positive condition is also associated with spawning (Fig. 11A) after which condition declines, normally becoming negative. Periods of negative condition also occur during times of reduced food availability, such as in winter (Fig. 9D). At these times, weight decreases as the hard clam resorbs tissue to cover metabolic needs and length remains constant (Fig. 11A). After simulation year 5, the variability in condition index is reduced (Fig. 11B) because of less frequent spawning. After the first five simulation years (clam age of 7 y) the trend in condition index is negative, with only occasional short-duration periods of positive condition. Condition index remains negative after simulation year 9 (clam age of 11 y).

The negative condition characteristic of the latter stages of hard clam development is expected. Growth slows with increasing age because the time-integrated amount of energy assimilated begins to be balanced by the losses to respiration and reproduction. For the simulated shell growth to slow, as observed at old age, condition index must rarely rise above zero, as positive condition leads to shell growth. The expected rise and fall of condition index with the yearly gametogenic cycle (Fig. 11B) differs from the overall trend in relative condition over the animal's lifetime that describes the decline in growth efficiency as animal size increases (Thompson & Bayne 1974, Hawkins & Bayne 1992, Brown et al. 1993, Lika & Nisbet 2000). This constraint in energy apportionment is also seen in spawning. Spawning is a frequent and regular event during the first four simulation years (clam age of 2–6 y) of the representative animal and spawning season spans much of the summer (Fig. 12A). The number of eggs spawned increases during the first four simulation years (Fig. 12A). In subsequent years, spawning normally occurs once yearly and the number of eggs produced is relatively constant.

Individual Hard Clam Reference Simulation—Sensitivity Studies

Exposure to a six-month period without food (Fig. 9D), beginning at the start of simulation year 3, produces starvation and results in a cessation of hard clam growth (Fig. 11A), reduced spawning frequency and egg production (Fig. 12B), and an extended period of negative condition index (Fig. 13). Once food is again available, length increases (Fig. 11A). Spawning frequency and egg production in the following two simulation years (years 4 and 5) is more frequent than observed in the nonstarved simulation (Fig. 12A,B). An additional starvation period in simulation year 6 again results in cessation of growth but the final hard clam length after 10 y of simulation is similar to that obtained from the simulation in which food was available at all times. This rebound effect is well known (e.g., Engle & Chapman 1953, Kobayashi et al. 1997) and originates from the inherently higher growth efficiencies of smaller animals that allows them to appear to "catch up" in growth when energy limitation ceases. Again, spawning frequency and egg production are reduced by starvation (Fig. 12B). Although starvation events do not seem to have a long-term effect on hard clam growth, as indicated by length, there is an effect on reproductive capacity (Fig. 12B).

An assumption made in the development of the individual-based model is that small hard clams have lower assimilation efficiency (Eq. 13). The importance of this assumption is demonstrated by a simulation in which the assimilation efficiency of small hard clams was not reduced. In the first 0.5 y of the simulation, when individuals are less than 30 mm, condition index exceeds 0.5 (Fig. 13), a value well above the condition index

Figure 11. Simulated time development in (A) hard clam weight and length obtained from the reference simulation and a simulation that included a starvation period (cf. Figure 9D) and (B) condition index obtained from the reference simulation. Note that weight and length are given on log and linear scales, respectively.

Figure 12. Simulated change in the timing and magnitude of the number of eggs spawned by hard clams exposed to (A) standard food conditions and (B) standard food conditions with an imposed starvation period (Figure 9D).

obtained from the simulation that assumed reduced assimilation efficiency (Fig. 11B). The resultant growth rate for small hard clams is unrealistic.

Hard Clam Cohort Simulations

Hard Clam Cohort Reference Simulation—Basic Characteristics

The individual hard clam simulations were combined via Eq. (17) to produce a cohort with genetic variation imposed through variability in assimilation efficiency and initial length. The length-frequency distribution of the cohort produced from the individual-

Figure 13. Simulated change in hard clam condition index that occurs in response to relaxing the constraint of reduced assimilation efficiency for small clams (Eq. 13) and to imposing a starvation period (Figure 9C).

based reference simulation (Fig. 14A) shows an initial large peak at 25 mm that decreases in amplitude as the cohort ages and mortality has an effect. The range of lengths included in the cohort increases with age. For example, the cohort in simulation year 4 (clam age year 6) ranges from about 30 mm to almost 75 mm. This expansion of cohort length range with age is well described (Craig & Oerel 1966, Powell et al. 2005).

Cohort biomass (Fig. 14B) begins to increase in simulation year 2, peaks in simulation years 4 and 5 (clam age years 6 and 7) as growth exceeds mortality, after which it decreases to low levels in simulation year 15 and beyond. Cohort egg production is highest in simulation years 2–5 (clam age years 4–7), and declines in later years (Fig. 14B). Much of this trend originates from the increase in fecundity of young clams as they grow and the decline in cohort fecundity with age, as the clams die. The number of survivors in the cohort declines over the simulation, reaching essentially zero after simulation year 12 (Fig. 14B).

Hard Clam Cohort Reference Simulation—Sensitivity Studies

The effect of reduced and increased range in genetic variability on cohort structure was tested. Genetic variability was modified by changing the values of σ_{C1} and σ_{C2} in Eq. (17): smaller values yield a restricted range and larger values give an expanded range. The cohort structure produced by a restricted range of genetic variability (Fig. 15A) is similar to that obtained from the basic simulation (Fig. 14A), but with an unrealistic reduction in the spread in length within the individual cohorts. The number of individuals in the modal size class of the cohort is larger than that obtained in the reference simulation because the narrow range of genetic variability retains more individuals in a narrower range of length classes. The expanded range of genetic variability results in

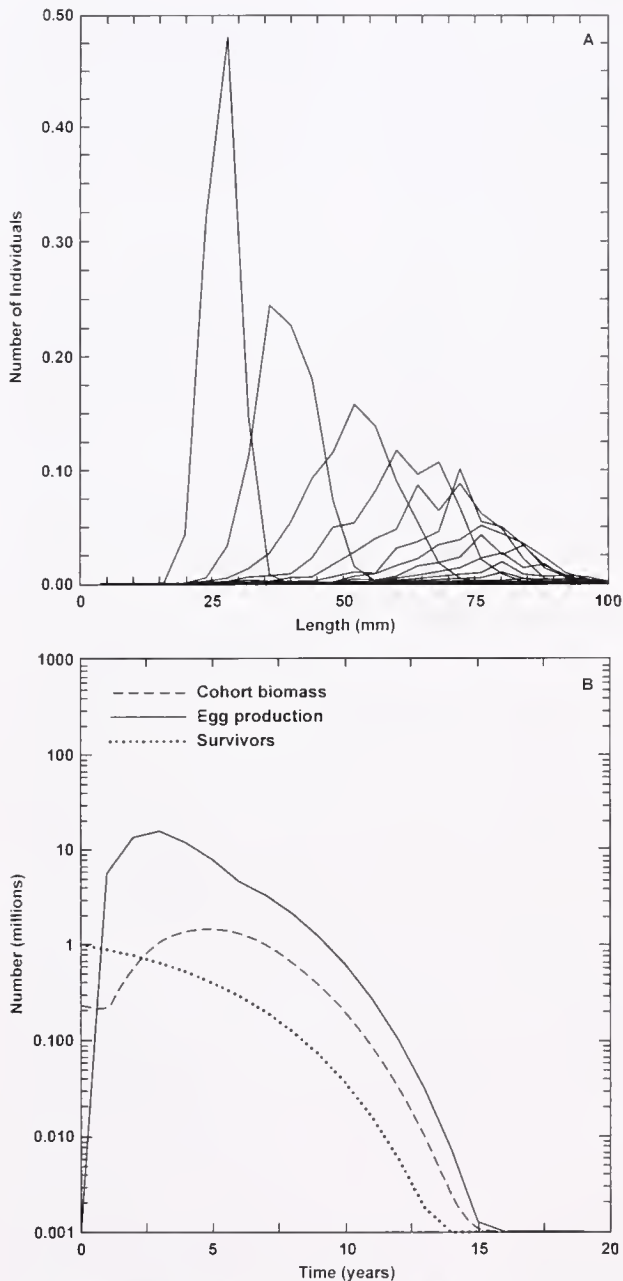

Figure 14. Simulated (A) length-frequency distribution and (B) time development of cohort biomass, egg production, and recruitment constructed from results of individual hard clam simulations subject to the standard environmental conditions (Figure 9) and standard genetic range for initial length and assimilation efficiency (Table 2).

considerable, and again unrealistic, spreading of the cohort (Fig. 15B). Cohorts for simulation years 4 and higher (clam age years 6 and higher) essentially include animals of all lengths.

Respiration rate is another physiological characteristic that produces genetic variability in hard clams. Variation in respiration rate and initial length produces a cohort structure (Fig. 16A) that is similar to that obtained using assimilation efficiency and initial length, but the number of individuals in the older cohorts is too large.

The cohort structure that results when respiration rate and assimilation efficiency are varied together is also unrealistic (Fig.

Figure 15. Simulated length-frequency distribution obtained for a hard clam cohort for (A) a reduced range of genetic variation imposed by setting σ_{c1} and σ_{c2} in Eq. (17) to 1.5 for initial length and 0.075 for assimilation efficiency, respectively, and (B) an expanded range of genetic variation imposed by setting σ_{c1} and σ_{c2} in Eq. (17) to 6.0 for initial length and 0.3 for assimilation efficiency.

16B) because the length range of 2-y-old clams at the beginning of the simulation is not adequately represented by a single initial length. The length effect disappears in later simulation years to produce cohort length distributions that are similar to those obtained by variations in assimilation efficiency and initial length (Fig. 14). Assimilation efficiency and respiration are in many ways equivalent physiological processes because each varies scope for growth. However, assimilation efficiency introduces a wider range of variability in cohort length structure and more accurately reproduces known cohort length structures, when only a single physiological characteristic is considered.

The interaction between clam initial length and variation in physiological rate is reflected in the distribution of clam lengths in the cohort at age 7 (simulation year 5). Low assimilation efficiency

Figure 16. Simulated length-frequency distribution obtained for a hard clam cohort in which the population characteristics used to represent genetic variability were (A) initial clam length and respiration rate and (B) respiration rate and assimilation efficiency. The values of the genetic ranges are given in Table 2. The range of variation in respiration rate was assumed to be the same as for assimilation efficiency.

(less than 0.75 of the mean) results in hard clams that are <48 mm after 5 y, for all initial lengths (Fig. 17A). Production of clams larger than 85 mm requires assimilation efficiencies that are >1.25 times the mean rate, which gives a greater scope for growth. Variation of respiration rate over the same range gives larger clams for the same amount of change than does variation in assimilation efficiency (Fig. 17B). The implication is that larger clams are the more metabolically efficient, with lower weight-specific respiration rates. Changes in initial clam length for a given variation in respiration rate produce minor, but important modifications, to these trends.

The effect of variations in assimilation efficiency and initial length on total egg production is to constrain genotypes characterized by low assimilation efficiency and small initial size (Fig. 18A). Because more clams have average genotypes, the Gaussian-

Figure 17. Simulated final length (mm) obtained for a hard clam cohort after five simulation years in which the population characteristics used to represent genetic variability were (A) initial clam length and assimilation efficiency and (B) initial clam length and respiration rate. The x-axis values represent the fraction of the mean value of all cohort genotypes as expressed by Eq. (17). The range in variation for respiration rate was assumed to be the same as for assimilation efficiency.

weighted egg production of the cohort will be highest near the center of the distribution, all else being equal. Assimilation rates (Fig. 18A) that are lower than the mean rate (<1) compress the Gaussian distribution, as these animals' scope for growth is insufficient to permit normal fecundity. Similarly, respiration rates that are higher than the mean rate (>1) (Fig. 18B) compress the Gaussian distribution, as high respiration debits energy that might oth-

erwise go into reproduction. The Gaussian-weighted egg production produced from the combination of respiration and assimilation efficiency rates (Fig. 18C) is slightly off center, indicating that the dominate members of the cohort responsible for reproduction are not the numerically most common genotypes. The most common genotype is at the center of the diagram (1.0, 1.0), whereas the center of egg production is below and to the right of this point (1.1, 0.95).

Hard Clam Population Simulations

Hard Clam Population Reference Simulation—Basic Characteristics

Concatenation of the yearly cohorts produced over a twenty-year simulation (Fig. 19A) results in a simulated hard clam population structure with two distinct abundance peaks centered around 25 mm and 40 mm and two smaller peaks at 60 mm and 70 mm. Highest abundance is associated with the newest cohort of 2-y-old clams at 25 mm modal size. The number of individuals at a given length (Fig. 19B) shows that most of the population is between 25 mm and 70 mm. For lengths greater than 70 mm, the number of individuals decreases as old-age mortality takes a toll.

The relationship between hard clam biomass and abundance (Fig. 19C) describes a trajectory that is followed as yearly cohorts are added to the population. The hard clam population initially peaks at about 2 g biomass and 0.8 individuals m^{-2} in year 4, after which it approaches a stable biomass of 6–7 g at an abundance of about 0.75 individuals m^{-2} . The population fluctuation that occurs as the first few cohorts are added is an artifact of model initialization and adjustment. The stability in the population after this adjustment represents a balance between the supportable biomass, the weight-dependent decline in fecundity in older clams, and the broodstock-recruitment relationship. Thus, the environmental conditions used in the reference simulation can support 6–7 g of hard clams, either as a few large or many small clams. The final simulated population abundance is typical of present day Great South Bay hard clam populations (Kraeuter et al. 2005).

The characteristics of the simulated population length frequency stem from an initial mode, centered around 25 mm (lower left, Fig. 20A), which moves towards larger lengths over time. This

mode is associated with the initial cohorts, which increase in length during the first few years of the simulation. After the initial adjustment years, the fraction of the population at a given length is relatively constant. A second mode appears after simulation y 4, again centered at 25 mm, which represents new recruits, which increase in length over time and are gradually absorbed into the larger length classes established by the initial cohorts. The hard clam population age-length structure after 20 y of simulation (Fig. 20B) shows that the fraction of the population at a given length spreads in age with increasing length and that the fraction of the population at a given age spreads in length as the population ages.

Hard Clam Population Reference Simulation—Sensitivity Studies

The simulated population structure is dependent on the form used for the broodstock-recruitment relationship (Eq. 30). Thus, the sensitivity of the population structure to different forms of this relationship was tested. The population structure that is produced by a broodstock-recruitment curve with no density-dependent control on population growth (Fig. 21A) shows more individuals m^{-2} and proportionately more smaller clams than obtained from the reference simulation (Fig. 19A). An equilibrium is not reached as each year sees an increase in the abundance of nearly all size classes (Fig. 21A). As a consequence, the population abundance at the end of the simulation is higher than observed for Great South Bay hard clam populations (Fig. 21B). The population age-length relationship is elongated towards larger animals (Fig. 22A) and curves upwards in age. The curvature indicates that large animals achieve higher abundance, which is consistent with no density-dependent controls. This is further indicated by the population trajectory (Fig. 22B), which shows an unconstrained increase in population biomass and number of individuals m^{-2} over the 20-y simulation.

Increasing the strength of the density-dependent control in the broodstock-recruitment relationship results in a simulated population structure in which the number of individuals m^{-2} (Fig. 23A) and the biomass (Fig. 23B) are reduced relative to the reference simulation (Fig. 19A, B). The relationship between population biomass and abundance (Fig. 23C) shows an initial adjustment, after which the population reaches a stable value of about 4 g at 0.4

Figure 18. Egg production (contours are \log_{10} eggs produced) after five simulation years for a hard clam cohort with genetic variability introduced through variations in: (A) initial clam length and assimilation efficiency, (B) initial clam length and respiration rate and (C) respiration rate and assimilation efficiency. The x-axis values represent the fraction of the mean value of all cohort genotypes as expressed by Eq. (17). The range in variation for respiration rate was assumed to be the same as for assimilation efficiency. The number of eggs produced by a cohort is determined by the fecundity of the individual hard clam and the abundance of the genotype in the cohort.

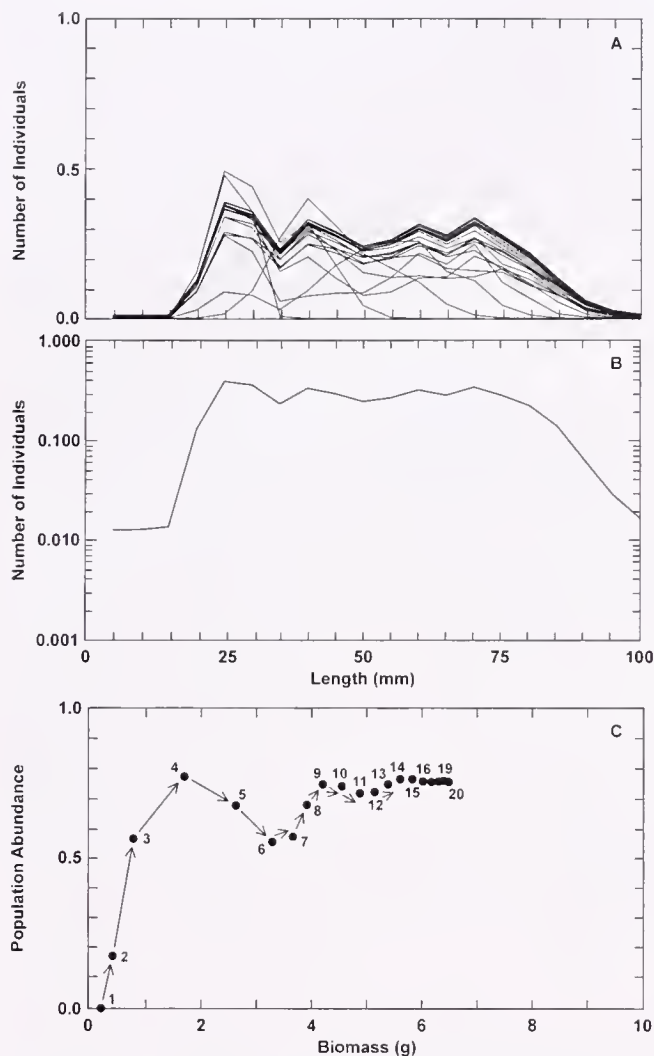

Figure 19. Simulated (A) population structure produced by summing a series of cohorts in which each line represents the length frequency of the population in a given year, (B) number of individuals at a given length in the population on a log scale and (C) the time history of population abundance as a function of biomass for hard clam populations exposed to the standard environmental conditions (Fig. 9) and for which genetic variability was represented by initial clam length and assimilation rate (Table 2). The superposed lines in the length-frequency distribution (A) identify the most stable age structure for the population.

ind m^{-2} and a stable length frequency (Fig. 23A). Abundance is too low, however, relative to observed hard clam population abundances in Great South Bay.

Natural mortality rate also affects the simulated population structure. Increasing the mortality rate for 40- to 60-mm hard clams produces a stable population structure (Fig. 24A), but the number of individuals m^{-2} at a given length is about an order of magnitude less than that obtained for the reference simulation (Fig. 24B versus Fig. 19B). The population abundance as a function of population biomass stabilizes at a value of about 0.05 g and 0.15 ind m^{-2} (Fig. 24C), values much below those observed for Great South Bay hard clam populations. Removal of the intermediate-size clams at an increased rate skews the population age-length relationship (Fig. 25) towards smaller lengths and younger ages by limiting the number of animals that grow to large size.

Figure 20. Simulated change in hard clam population length as a function of (A) simulation time, showing the maturity of the population length structure and (B) hard clam age, showing the age-length structure of the mature population after 20 y of simulation time. Contours are number of individuals m^{-2} .

Increased mortality of 60- to 80-mm hard clams results in a population that stabilizes at a biomass and abundance (Fig. 26A) of about 1.3 g and 0.36 ind m^{-2} , respectively, still well below Great South Bay observations, but higher than the 40-60 mm simulation (Fig. 24) because fecundity per g dry wt is highest in clams of this latter size range and so recruitment is increased. The age-length structure of the population is truncated at lengths above 60-70 mm and ages in excess of simulation years 4 and 5, which correspond to clam age years of 6 and 7 (Fig. 26B).

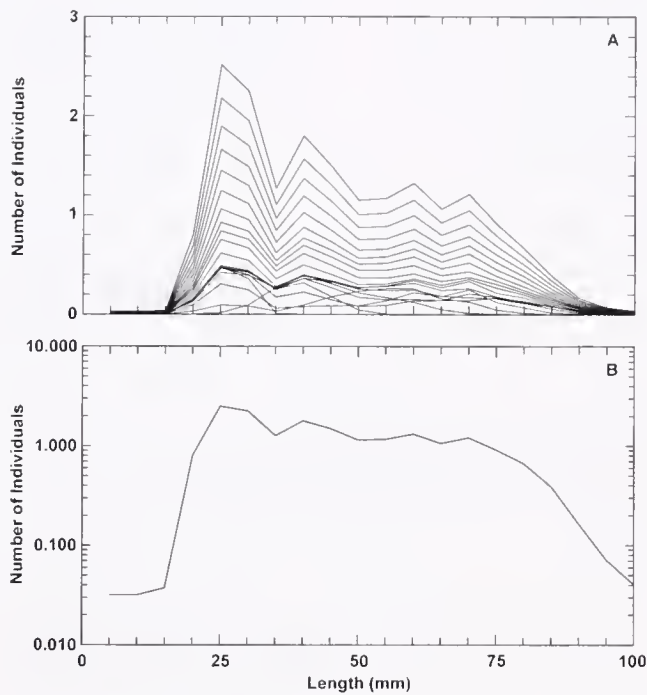

Figure 21. Simulated (A) population length frequency in which each line represents a yearly state of the population and (B) the number of individuals at a given length obtained for a hard clam population in which the density-dependent constraint in the broodstock-recruitment relationship was removed.

Simulated Age-length Relationships

The age-length distribution obtained from the reference simulation (Fig. 27A) shows an almost linear relationship between length and age for hard clams between 20 and 40 mm, after which the increase in length for an incremental increase in age slows, giving a curvature to the distribution. The upward curvature of the age-length distribution is produced by reduction in growth rate with increasing length, which is consistent with observations (e.g., Ansell 1968, Loesch & Haven 1973, Devillers et al. 1998). Older hard clams do not increase in length as rapidly as they age. The newest two cohorts (2- and 3-y-old animals, simulation ages of 0 and 1 y) establish discrete modes in the population length- and age-frequency distribution; older cohorts meld into a single mode characterized by decreasing numbers as the older cohorts age (Fig. 27A).

The distribution of lengths obtained from sections across the age-length relationship at given ages produces a typical length-frequency diagram that becomes increasingly skewed with increasing cohort age (Fig. 27B). The tail of the distribution extends towards smaller length classes because some genotypes grow slowly and hence continually fall behind the cohort modal length. The differential growth rates of the individuals in a cohort produces, in part, the asymmetric distribution in age-length space (Fig. 27A) that is skewed towards smaller lengths and older ages. Sections through the hard clam age-length distribution at specific lengths shows that the age distribution becomes increasingly skewed at increasingly larger lengths (Fig. 27C). The long tail that extends towards older age classes occurs because the rate of natural mortality increases with clam age. The assumption that a cohort (or length class) has a Gaussian distribution of lengths (ages) is

Figure 22. Simulated (A) age-length relationship and (B) the time history of population abundance as a function of biomass obtained for a hard clam population in which the density-dependence constraint in the broodstock-recruitment relationship was removed. Contours are number of individuals m^{-2} .

correct for smaller ages (lengths) (Craig & Oertel 1966), but the Gaussian approximation becomes increasingly less accurate at older ages and larger lengths.

The hard clam model provides a framework for ascribing causes to shape variations in age-length distributions. Variations in cohort growth rates expand (Fig. 28A) or contract (not shown) the population expression in age-length space along the long axis. Faster growth tends to maintain the Gaussian shape of the age-

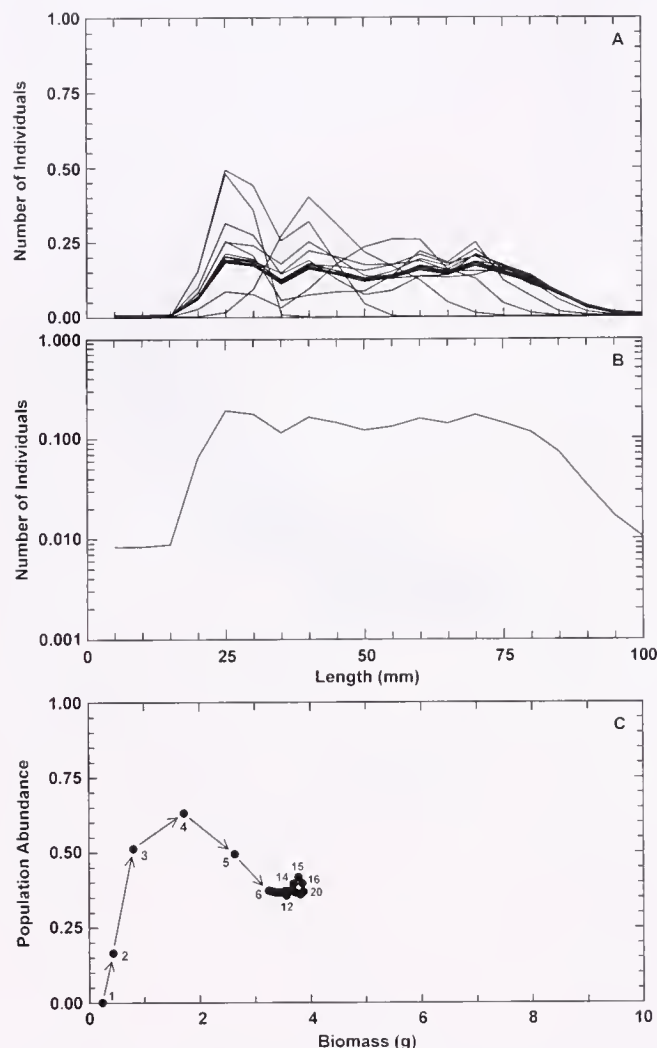

Figure 23. Simulated (A) population length frequency in which each line represents a yearly state of the population, (B) the number of individuals at a given length and (C) the time history of population abundance as a function of biomass for a hard clam population in which the density-dependence constraint in the broodstock-recruitment relationship was increased.

frequency and length-frequency distributions (Figs. 28B, C); whereas, slow growth tends to exaggerate the asymmetry in both directions.

Decreased adult mortality rate yields an age-length distribution (Fig. 29A) that is similar to that obtained for the reference simulation (Fig. 27A). However, the asymmetry in the age-frequency distribution is greater because of the tendency for age-dependent mortality to be biased towards older ages regardless of length. A decrease in mortality rate has only a minor influence on the length frequency for a given cohort (Fig. 30A), because mortality is apportioned by cohort; that is, mortality is age-dependent rather than length dependent. In contrast, the age frequency for a given length (Fig. 30C) varies from the reference simulation. In this case, a larger fraction of animals in the larger length classes (e.g., 70 mm) are represented by the oldest clams.

Increased adult mortality rate results in an age-length distribution that is compressed in age for a given length (Fig. 29B). However, the length frequency at age is similar to that from the reference simulation (Fig. 27B) and the decreased adult mortality simu-

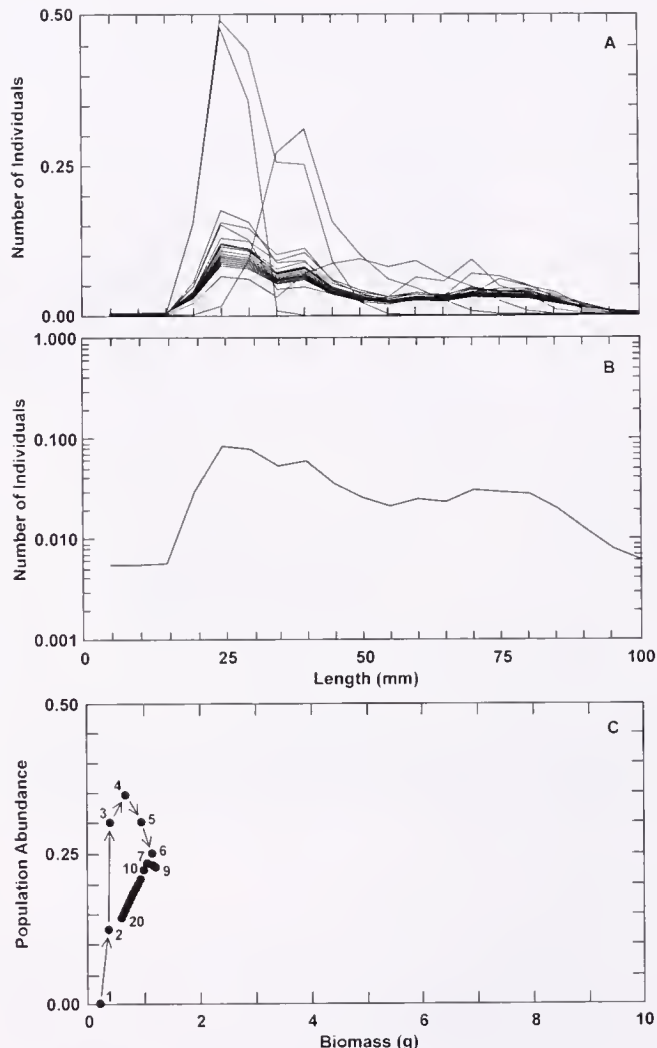

Figure 24. Simulated (A) population length frequency in which each line represents a yearly state of the population, (B) the number of individuals at a given length and (C) the time history of population abundance as a function of biomass for a hard clam population in which mortality imposed on the 40- to 60-mm clams was increased.

lation (Fig. 30A) because relatively more large animals are old, which truncates the length frequency at large size. The age frequency at length (Fig. 30D) is less skewed than in the reference simulation (Fig. 27C) because the older animals that add skewness to the distribution are present in much lower numbers.

Reducing recruitment by half in the last five years of the simulation narrows the age-length distribution at small length (Fig. 31A). In this simulation, a smaller fraction of the population is represented over a range of age-at-length (Fig. 31B) and length-at-age (Fig. 31C) distributions. Relative to the reference simulation (Fig. 27B), the length frequencies of older clams are unchanged, whereas the length frequency of the 2-y-old cohort is muted by reduced recruitment. In contrast, all age frequencies are muted in comparison with the reference simulation (Fig. 27C) because some animals at nearly all lengths were ≤ 5 y old. Hence, the distribution of age-at-length has been affected more than the distribution of length-at-age.

The shape of the hard clam population age-length distribution is also controlled by the cohort genetic composition. A restricted

Figure 25. Simulated age-length relationship for a hard clam population in which mortality imposed on the 40-to-60-mm clams was increased. Contours are number of individuals m^{-2} .

proportion of slow and fast growers in the cohort, which reflects numerical abundance of a narrow range of genotypes, yields a markedly different population structure (Fig. 32A). This age-length composition is similar to that obtained with increased

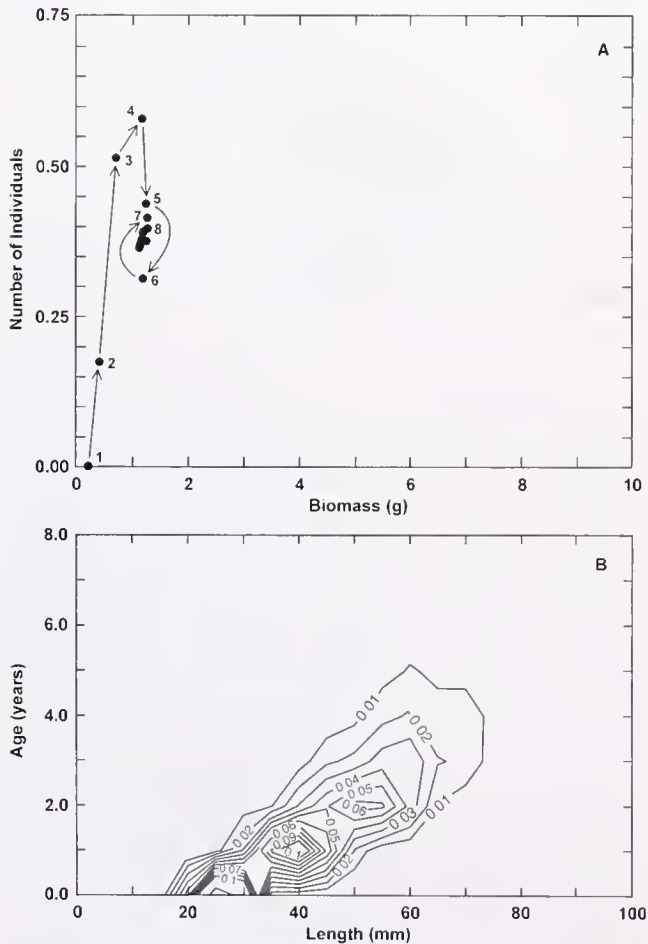

Figure 26. Simulated (A) time history of population abundance as a function of biomass and (B) age-length relationship for a hard clam population in which mortality imposed on the 60-to-80-mm clams was increased.

growth rate (Fig. 28). The degree of bending along the long axis is increased with respect to the reference simulation (Fig. 27A) because more individuals in the cohort have the average genotype and this also constrains the width of the age-length distribution in

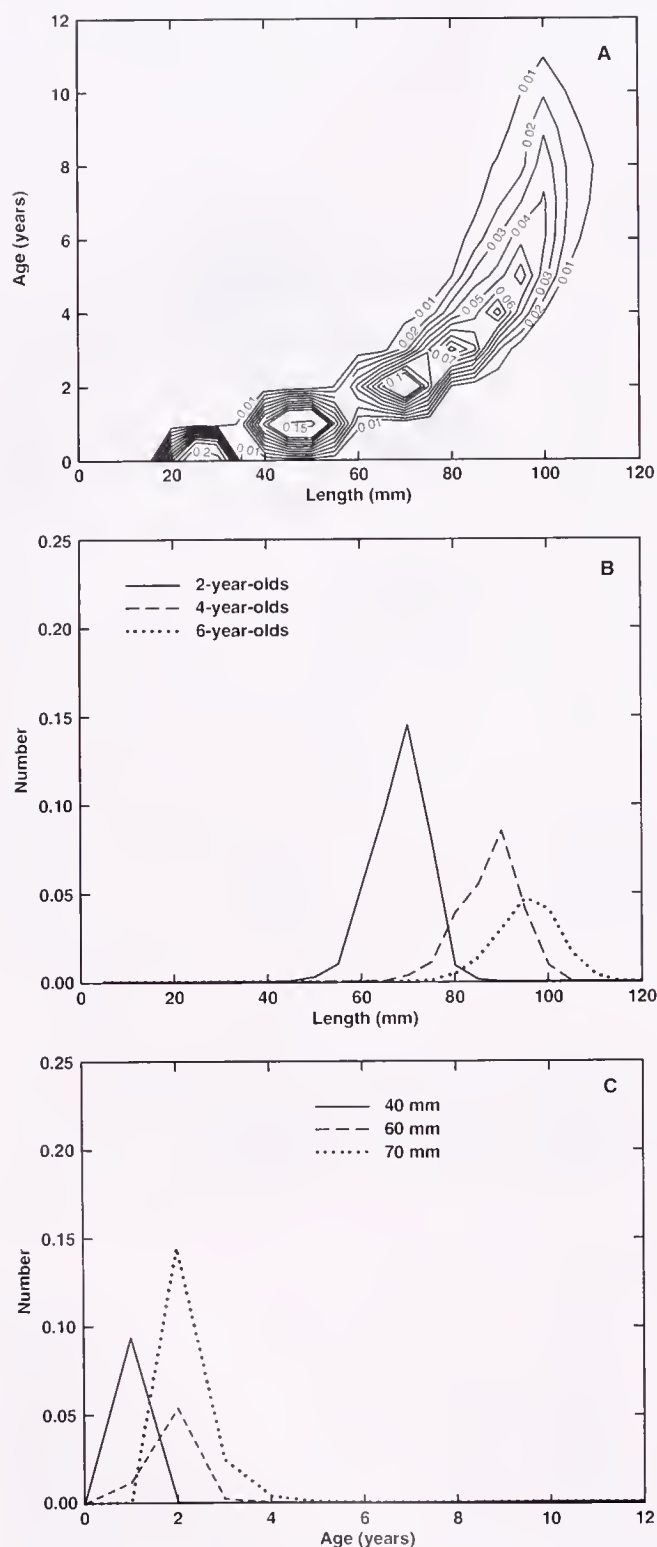

Figure 28. Simulated (A) age-length (B) length-at-age and (C) age-at-length frequency distributions obtained when the population growth rate is increased. Contours are number of individuals m^{-2} .

age-length space. The range of lengths at age is small, as is the range of ages at length. Because the increase in length ceases relatively uniformly within the cohort, the increment in age for a given increment in length increases with age, producing a strongly curved age-length distribution.

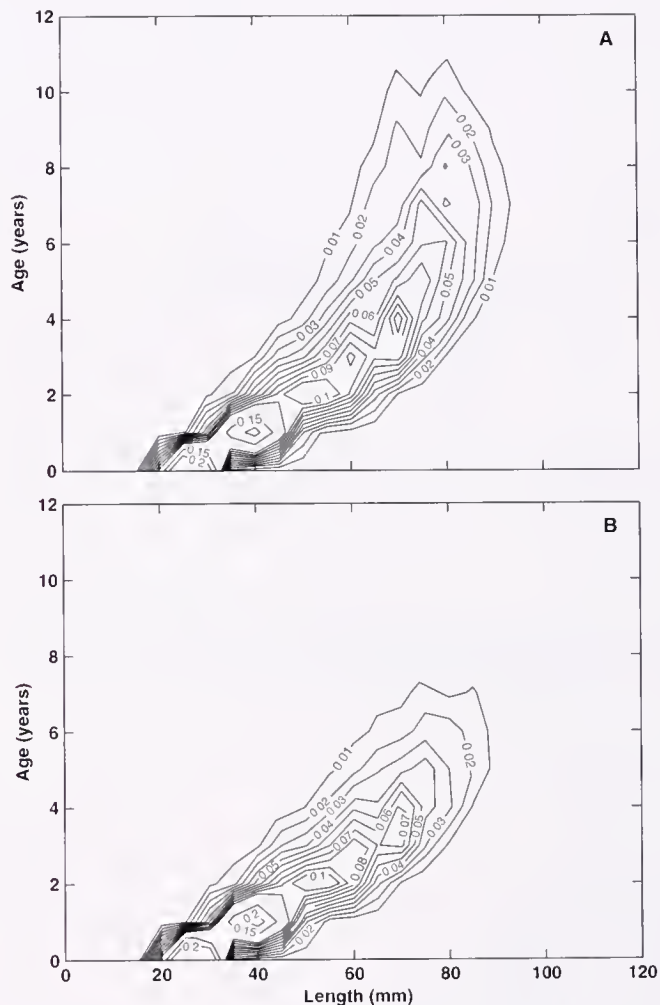

Figure 29. Simulated age-length distributions obtained when adult mortality rate is A) decreased and B) increased. Contours are number of individuals m^{-2} .

An expanded proportion of slow and fast growers in the cohort, which provides more even representation of genotypes, substantially changes the appearance of the hard clam population (Fig. 32B). The degree of bending along the long axis is lessened because more individuals in the cohort grow faster at older age. However, more individuals in the cohort also grow slower at older ages. As a consequence, the age-length distribution expands along both axes. The range of lengths at age is wider, as is the range of ages at length. These two trends straighten the shape of the population structure in age-length space, but also truncate the length of the long axis because fewer very-old and very-large animals exist.

Development of General Age-length Relationship

The age-length distributions obtained from the simulated populations (Figs. 27, 28, 30, 31, 32) have common characteristics. Each is inclined at an angle to the age-length axes, the long axis typically twists upwards, and the asymmetry along the long axis typically increases with progression towards older, larger clams. The asymmetry in these age-length distributions is internally consistent in that a more restricted length and age range of clams falls on the younger and larger side of the long-axis ridge. The curvature in the location of the ridge as the clams get older indicates that a maximum length exists for the population and that older clams

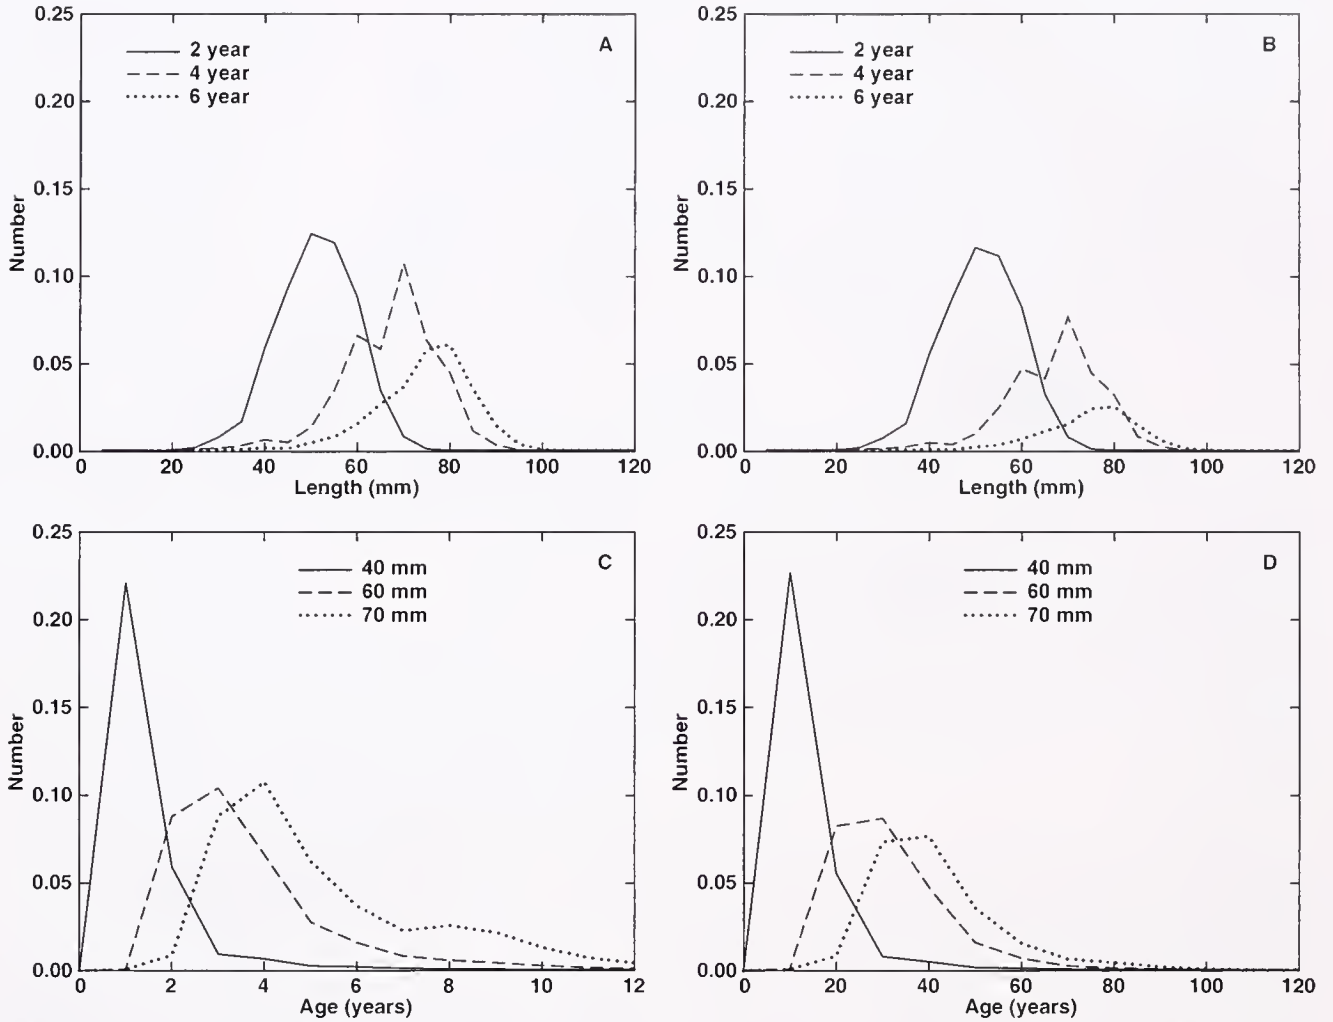

Figure 30. Simulated age-at-length obtained for (A) decreased and (B) increased adult mortality rate and simulated length-at-age obtained for (C) decreased and (D) increased adult mortality.

live for a while near their largest length. The age-at-length and length-at-age slices through the various age-length relationships show that these follow an approximate Gaussian distribution (e.g., Fig. 30). The similarity in the form of the various age-length distributions obtained from simulations that included a range of different processes suggests that they can be described by a general mathematical relationship, as developed in the following sections.

Formulation of a Twisted Bivariate Gaussian Functional Form

The structure of the age-length relationship can be reproduced by a bivariate Gaussian function that includes the capabilities for curvature at increasing age and length and for variability in the distribution about a given age or length. The bivariate Gaussian function was implemented in a rotated coordinate system (x, y) that is aligned along the axis of the maximum in the length-age (L, A) distribution in the original coordinate system (Fig. 33). The alignment is done using a coordinate rotation angle θ , which shifts the new coordinate system counterclockwise relative to the age axis. The rotated coordinate system is centered around a central age (A_o) and length (L_o) that are representative values associated with the maximum in the age-length distribution. These parameters control the location of the origin of the rotated coordinate system relative

to the original age-length distribution. The x and y axes in the rotated coordinate system are scaled by the factors S_A and S_L , which allows matching of the magnitude of the age and length values in the two coordinate systems. The coordinate transformation is:

$$\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix} \cdot \begin{pmatrix} S_L(L - L_o) \\ S_A(A - A_o) \end{pmatrix} \quad (31)$$

and the correspondence between the original age-length coordinate system and the rotated coordinate system is shown in Figure 33.

The transformed coordinate system aligns the age-length distribution so that it can be fit with a bivariate Gaussian function to obtain the number of individuals m^{-2} at a given length and age, $N(x, y)$, as:

$$N(x, y) = N_0 e^{\frac{-x^2}{2\sigma_x^2}} e^{\frac{-(y-y_m)^2}{2\sigma_y^2}} \quad (32)$$

where N_0 is the maximum number of individuals m^{-2} at zero age, x and y are the transformed length and age axes, respectively, and σ_x and σ_y determine the spread of the Gaussian, the standard deviation, along the length and age distribution, respectively. The

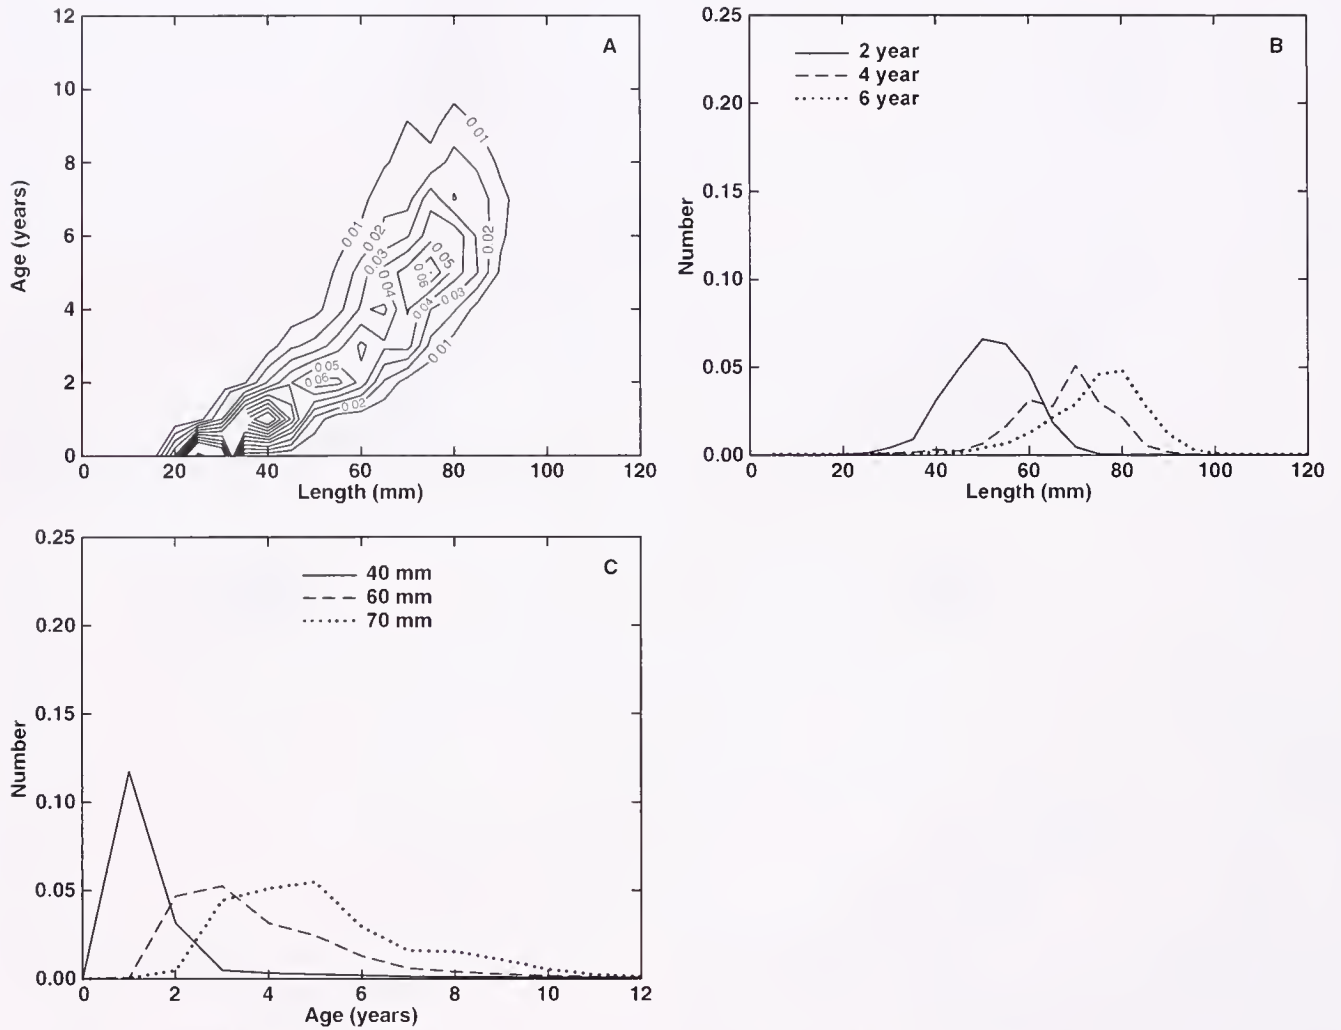

Figure 31. Simulated (A) age-length (B) length-at-age and (C) age-at-length frequency distributions obtained when the recruitment rate is decreased. Contours are number of individuals m^{-2} .

parameter y_m is the center of the Gaussian distribution along the rotated age axis (y).

The typical age-length distribution (e.g., Fig. 27A) has three additional features that need to be included in Eq. (32). First, the ridge in age-length space curves upward for older and longer clams. The curvature of the age-length distribution at older and longer clams is introduced by allowing the center of the Gaussian distribution, given by y_m , to change as a function of the rotated x coordinate:

$$y_m = a x^n \quad (33)$$

which shifts the centroid of the Gaussian towards positive y with increasing x , with the degree of curvature determined by n (Fig. 33). This modification to y_m provides the twist to the bivariate Gaussian.

Second, the age-length distribution has a shallower slope (is wider) for older (longer) clams relative to younger (shorter) clams, which produces an asymmetric distribution. The asymmetry in the spreading of the age-length distribution about the maximum ridge value is created by allowing σ_y to vary along the rotated age axis (y).

Third, the width of the age-length relationship increases for older and longer clams. The spreading of the age-length distribu-

tion for older and longer clams is created by increasing the value of σ_y with distance along the rotated length axis, x , as:

$$\sigma_y(x, y) = \begin{cases} S1 (1 + b1 x), & \text{if } y - y_m > 0, \\ S2 (1 + b2 x), & \text{if } y - y_m < 0 \end{cases} \quad (34)$$

where the parameters $S1$, $S2$, $b1$ and $b2$ are obtained from fitting the general age-length relationship to an age-length data set, as described in the following section. This modification allows $\sigma_y(x, y)$ to have different values on either side of the maximum ridge value, y_m .

The addition of the above modifications to Eq. (32) gives a twisted bivariate Gaussian of the form:

$$N(x, y) = N_o e^{\frac{-x^2}{2\sigma_x^2}} e^{\frac{-(y-y_m(x))^2}{2\sigma_y(x,y)^2}} \quad (35)$$

The application of Eq. (35) to determine age-length distributions is described in the following section.

Functional Fitting Procedure

The twisted bivariate Gaussian function (Eq. 35) has 13 parameters that need to be specified to create an age-length distribution. The coordinate scaling factors (S_L , S_A) and the Gaussian width in the same direction (σ_x , σ_y) are not independent param-

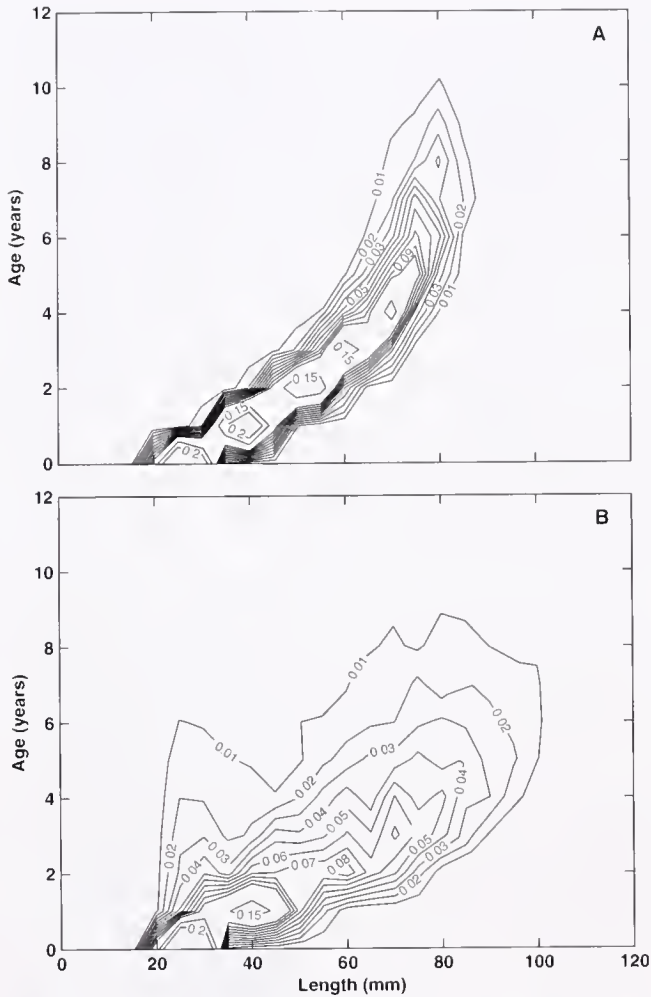

Figure 32. Simulated age-length frequency distributions obtained when the range of assimilation efficiency genotypes was (A) narrower and (B) broader in comparison with the reference simulations. Contours are number of individuals m^{-2} .

eters, so the values of S_L and S_A were specified and the Gaussian width parameters were determined. The rotated (x, y) coordinate system is constrained to be on the $A = 0$ axis by choosing $A_0 = 0$. The remaining 10 parameters (Table 4) need to be determined.

The parameter fitting procedure is based on minimizing the difference in hard clam age-length distributions obtained from observations and those obtained from the twisted bivariate Gaussian model (Eq. 35). Prior to the start of this procedure, the age-length data sets were filtered relative to a threshold value because many age-length combinations do not occur in hard clam populations. These combinations were removed from the input data sets by setting a minimum length criterion for each age-length combination. For this study, the maximum clam density in the simulated age-length distributions, which is controlled by the total number of clams in the population model, is 0.25 clams of a given age and length m^{-2} . The threshold value for the age-length distributions was set at 6% of this maximum value, 0.015 clams m^{-2} .

The parameter fitting procedure is based on minimizing the sum square deviation between the observed number of clams m^{-2} (N_i^o) and the theoretically-derived number of clams m^{-2} (N_i^f , obtained from Eq. 35) for a given length (L_i) and age (A_i) as:

Figure 33. Schematic of correspondence between the age-length coordinate system and the scaled age-length coordinate system used for the twisted bivariate Gaussian function. The axes (x, y) of the scaled coordinate system have an origin at (L_0, A_0) and are rotated relative to the original length and age axes by the angle θ . The curvature of the age-length distribution is given by y_m . See text for additional details of the scaled age-length coordinate system.

$$C = \sum_i (N_i^o - N_i^f)^2, \quad (36)$$

where C is a measure of the misfit between the observed and theoretical age-length distributions.

The minimization procedure is most efficient when started with initial parameter values that are near optimal values. The initial parameter values were estimated by an iterative procedure in which the minimum and maximum values for a particular parameter were used to set a range for the parameter. Values at 25%, 50% (midpoint) and 75% of this range were then determined and these along with the two extremes were used in Eq. (35) and the misfit between the theoretical and observed age-length distribution was determined with Eq. (36). The parameter set that produced the minimum misfit was taken as the initial parameter values and the minimization procedure repeated to yield a second estimate of the optimal parameter set. This parameter set was then used as initial values and the minimization procedure repeated a third time. The parameter values that were obtained from this minimization provide the starting point for a multidimensional minimization procedure, based on Powell's Method (Press et al. 1989), which produces the final optimal parameter set. This final parameter set provides the best fit of the twisted bivariate Gaussian model to a particular age-length data set. Once the optimal parameter set is determined, the twisted bivariate Gaussian model can be used to develop an age-length distribution that includes all ages and lengths.

Parameterization of Simulated Age-length Relationships

The age-length data sets obtained from the simulations in which growth, mortality and recruitment rates were varied, and in which the apportionment of individuals among genotypes was expanded and reduced, were used to fit the 10 free parameters for the twisted bivariate Gaussian function (Table 4). The resulting parameters were then used with Eq. (35) to produce age-length distributions (Fig. 34).

TABLE 4.

Optimal parameter values obtained from fitting the twisted bivariate Gaussian given by eq. (35) to different simulated hard clam population age-length data sets. The figure showing the corresponding age-length distributions is indicated.

	Reference Case	Decreased Growth	Increased Growth	Increased Adult Mortality	Decreased Adult Mortality	Decreased Recruitment	Reduced Genetics	Expanded Genetics

Figure 34. Age-length distributions obtained by fitting the twisted bivariate Gaussian formulation (Eq. 35) to the simulated age-length data sets obtained for a hard clam population in Great South Bay for: (A) the reference simulation, (B) increased growth rate, (C) decreased adult mortality rate and (D) even apportionment of genotypes, obtained by setting σ_{C_1} and σ_{C_2} in Eq. 17 equal to 0.25. Contours are number of individuals m^{-2} . The parameter values obtained from fitting the twisted bivariate Gaussian to the different simulated hard clam age-length data sets are given in Table 4.

The simulated age-length data sets produced with decreased growth rate, increased adult mortality, decreased adult mortality, and expanded genetic range resulted in optimal values for the central length (L_0) that are smaller than that obtained for the reference simulation age-length data set (Table 4). The value of L_0 determines where the x -axis of the rotated coordinate system intersects the length axis in the original coordinate system (Figs. 33 and 34). The value of this parameter indicates that the small animals have a smaller average size in these simulations than those in the age-length distributions obtained from the reference simulation. The age-length data sets from the increased growth-rate, reduced genetic range and decreased recruitment rate simulations gave an optimal L_0 that is larger than the value obtained from the reference simulation. This indicates that the small animals in these simulations are on average larger than those in the reference simulation.

The age-length distribution created by decreased growth rate yields values for L_0 , a , σ_L and $b2$ that are reduced relative to the values obtained from the reference simulation (Table 4). The parameter θ is unusually high. The parameters σ_L and $b2$ produce greater asymmetry in the length and age-frequency distributions, which skews these distributions towards smaller lengths and older ages. These characteristics are consistent with a slow growing hard clam population. The negative value for a indicates a tendency for old animals to grow slower at a given length and the high value of θ shows that age increases relatively rapidly for an increase in length. Collectively, no other simulated condition has values of L_0 , a , σ_L and $b2$ simultaneously this low and θ this high.

Increased growth rate creates a simulated hard clam population with an age-length distribution that is characterized by a combination of high L_0 , $S2$ and σ_L and low values for θ , a and negative $b2$. These parameters result in a narrow, elongated age-length distribution that intersects the length axis at a small angle (Fig. 28A). The curvature of the age-length distribution produced with increased growth rate is more pronounced than that from other simulations and as a result, the parameter (n) determining the curvature of y_m differs from the parabolic dependence obtained for the reference simulation and all other cases (Table 4). No other simulation has this unique set of parameters, the low values of $b2$ and a being particularly noteworthy.

A decrease in adult mortality yields high a , σ_L and $b2$ values, which produce an age-length distribution that has more curvature in the long axis and increased spread in age for a given length (Fig. 29A). The high value of σ_L distinguishes this simulation from another simulation with high a and $b2$ values, the simulation of a decreased range of genotypes (Fig. 32A), and this can be observed in Figure 29A by the broader range of values on the rotated x -axis of this simulation. Increased adult mortality (Fig. 29B) results in an age-length distribution with low σ_L and $S1$ values (Table 4). This combination of parameters gives an age-length distribution that is less spread out about the rotated y -axis and the rotated x -axis than the distributions produced by other parameter combinations.

The parameter fits from the simulation with lower recruitment in the last five years of the simulation (Fig. 31A) yield a lower value of $S2$ and an exceptionally high value of σ_L relative to the reference simulation (Table 4). These parameters control the spread of the Gaussian about the rotated x -axis and reduce the asymmetry about the y -axis. The narrowing of the age-length distribution at small length is an expression of this parameterization.

Increasing the relative abundance of slow and fast growing clams to the composition of the cohort, by increasing the evenness of the distribution of genotypes in the cohort, modifies all of the parameters that control the spread of the age-length distribution

about the long axis (Table 4). This combination of parameters gives an age-length distribution that is straighter and spreads out asymmetrically at older age and longer lengths (Fig. 32B). Reducing the distribution of genotypes in a cohort again modifies the optimal parameter set (Table 4) and produces an age-length distribution that is narrow and symmetric with age and length (Fig. 32A). Note the unusually low values of $b1$ and σ_L is unusually low for both of these genotype modifications, indicating the increased uniformity in cohort composition, caused in one case by the increase in abundance of genotypes rare in the reference simulation and the other by the decrease in abundance of the same genotypes.

DISCUSSION

Formulation of Model Processes

The hard clam simulations provide guidance for future research topics because formulations used for some processes included in the model differ from those routinely used in population dynamics models. Hard clam mortality was assumed to be age, not length, dependent. The filtration rate parameterization provides an asymmetric increase with increasing temperature up to a specified temperature, after which it declines sharply. These parameterizations were needed to obtain simulated growth rates for individual hard clams that matched observed rates.

Additional assumptions were made that affect the simulated cohort and population structure. These include parameterizations that limit fecundity as individual clam length increases and impose a temperature- and time-dependent control on the reproductive cycle. The concept of quality days was used to terminate hard clam reproduction so that the duration of the simulated reproductive cycle and egg production matched observations. That hard clam reproduction does cease in the fall is known. However, the basic physiological processes that result in cessation of reproduction are not known. This is one area highlighted by the model development where more research is needed.

The form of the broodstock-recruitment relationship places a strong constraint on how the cohorts are concatenated to form a population. The form chosen for this study is one of many possible approaches (Kraeuter et al. 2005). Specification of the appropriate form requires continued and long-term monitoring of hard clam populations.

The simulations show that chlorophyll a alone is not adequate to support hard clam growth, which is consistent with results from models developed for other shellfish (Soniati et al. 1998, Hyun et al. 2001). Comparisons with observations from Great South Bay show that the hard clam growth form (e.g., timing and rate of growth) is not adequately simulated by a chlorophyll-only food source, implying that alternative food sources are being used. This required that the food supply input to the model be modified to allow for nonchlorophyll food sources (cf. Fig. 9D). The nature and magnitude of the alternative food sources needed by hard clams is deserving of investigation and may be an important component of hard clam restoration efforts.

The individual-based hard clam model was developed for Great South Bay where salinity and turbidity variations are small and do not typically extend into ranges that inhibit metabolic processes. Application of the hard clam model to environments characterized by lower salinity or higher total suspended solid concentrations than are typical for Great South Bay requires further verification studies. In particular, little experimental data exist on the effects of salinity and its interaction with temperature and total suspended solids on hard clam physiology and metabolism.

Generalized Age-length Relationship

In individual shellfish, growth in age and length is partially decoupled. Growth rates within a cohort are such that many animals of differing ages may have the same length and many animals of differing length may have the same age. The age-length structure of a population is determined by a finite number of processes that control cohort length frequency, such as growth rate (Craig & Oertel 1966) and mortality rate, either of which may be age- or length-dependent. A small number of growth models routinely fit the length-age relationship of cohorts of a variety of species (e.g., Kappenman 1981, Kauffmann 1981, Tanabe 1988, Smith et al. 1997). The success of individual- and cohort-based growth models, such as the von Bertalanffy model, however, suggests that a few mathematical relationships might also describe the length-age relationships of populations. This study provides an example of the development of such a general relationship for hard clam populations.

Defining a general mathematical relationship that describes the age-length distributions allows development of age-length keys from fewer age-length measurements and application of age-length models. Moreover, population-to-population differences in the parameterization of the age-length model may be illustrative of important ecological and population dynamics processes determining the structure of the population just as variations in the parameters used in a von Bertalanffy growth model reflect differences in the structure of a cohort (e.g., Kornobis 1977, McCuaig & Green 1983, Nix et al. 1995).

Implications of a Generalized Age-length Relationship

The earlier mentioned analyses suggest that a twisted bivariate Gaussian function can successfully describe age-length distributions that are produced by modifications in hard clam population dynamics, including changes in growth rate, mortality rate, recruitment rate and cohort genotypic composition. The age-length characteristics of populations have not been fully investigated since the initial development of a theoretical growth model (Pütter 1920, von Bertalanffy 1938) in spite of numerous experimental and theoretical studies at the cohort level. Thus, the extent to which the present formulation can be extended to other shellfish and non-shellfish taxa remains unclear. The robustness of the formulation described by the twisted bivariate Gaussian may have general application for producing age-length distributions.

The different population processes that were used to produce the simulated age-length data sets used to test the twisted bivariate Gaussian yielded a unique set of parameter values that defined the angle of the long axis, the degree of curvature, the length of the relation along the twisted x axis, and the tendency for the y axis to spread asymmetrically about x (Table 4). These characteristics of the age-length distribution are controlled by the growth rates, the form of and degree of mortality imposed on the population, the stability of recruitment, and the inherent genetic composition of the recruits. These parameters provide information concerning the processes controlling the structuring of the population in much the same way as values of growth parameters (e.g., the von Bertalanffy k and L_{∞}) provide information on the processes controlling cohort growth. The extent to which the specific values of the parameters might be predictive of certain combinations of population dynamics cannot yet be determined, but the simulations presented here are encouraging of such an outcome. Obtaining a set of ages and lengths and then fitting the twisted bivariate Gaussian to these data, could potentially provide more insight into population processes than may be obtained from mul-

tiyear studies of the suite of complex population dynamics-determining processes that produce observed age-frequency distributions.

Measurements of length are easy to obtain, but age is the more often desired quantity and conversion of the one into the other requires age-length keys, which are time consuming to construct. As a result, more is known about length frequencies in natural populations than about the complementary age frequencies. The cost and time of obtaining age-length keys directly limit their use in fisheries management and in ecological investigation. As a consequence, little is known about how age-length properties of populations might change within metapopulations, along environmental gradients, or in response to long-term climate changes. For long-lived animals such as hard clams, the latter is particularly important.

Generating an age-length key requires information from many individuals of differing ages for a given length and many individuals of differing lengths for a given age (Fig. 27). Because the age-length distributions twist along the length axis and spreads asymmetrically, the age-length array must be filled over all lengths and ages. As a result, a simple statistical function will not have the flexibility to describe the variation in age with length or in length with age over all ages and lengths. For example, a simple Gaussian function will accumulate increasing error as age and length increase. In the larger length classes and older age classes, the increased rarity of the animals themselves imposes an additional constraint on the function used to describe age-length distributions. As a consequence, filling age-length key arrays with sufficient replicate measurements to describe the underlying statistical distributions is difficult.

The availability of a single mathematical formulation to describe age-length distributions for hard clam populations provides a significant advance in the ability to generate age-length keys. Many fewer individual age-length measurements are necessary, provided they are adequate representations of the population, to describe the age-length distribution. A sparser data set might be used to determine parameter values for the general mathematical formulation that then can be used to fill in the full age-length distribution needed for a key. The density of the data over the age-length spectrum of the population needed to do this requires further investigation, but tests done with the simulated age-length data sets produced in this study suggest that age-length keys could be created with tens rather than hundreds of age-length measurements. Should this prove to be the case, then the existence of a general mathematical formulation provides opportunity to investigate how age and length independently determine population structure beyond what has heretofore been possible to achieve. Furthermore, the twisted bivariate Gaussian expands the theoretical formulations defining the age-length character of the cohort into that of the population by identifying parameters analogous to the rate of length increase (k) and maximum length (L_{∞}) in the von Bertalanffy model (von Bertalanffy 1938, Fabens 1965, Kimura 1980). These parameters can now serve as the basis for theoretical models of population age-length compositions because they are determined by individual growth and mortality rates, but also by population-dependent processes, compensatory and otherwise.

RECRUITMENT PATTERNS AND PRECAUTIONARY EXPLOITATION RATES FOR GEODUCK (*PANOPEA ABRUPTA*) POPULATIONS IN BRITISH COLUMBIA

ZANE ZHANG* AND CLAUDIA HAND

Shellfish Stock Assessment Section, Pacific Biological Station, 3190 Hammond Bay Road, Nanaimo, British Columbia, V9T 6N7, Canada

ABSTRACT An age-structured projection model was used to study the impacts of alternative exploitation intensities on geoduck populations, based on a large accumulation of survey data, age composition data and published estimates of natural mortality. Data were analyzed and results presented by geographic region. Historic recruitment patterns were back calculated using an age-structured model. Trends in recruitment were independent of the value of M used, although rates were higher when M of 0.036 was applied compared with M of 0.016. Historic recruitment rates were found to be highly variable in the prefishery state: rates generally increased from the early 1930s to 1950, decreased until early 1960, increased to another peak in the mid 1960s, declined until the mid 1980s and have been increasing to present. Future recruitment was simulated from the estimated historic pattern. The fishing patterns examined were combinations of different mortality rates (0.016 or 0.036) and different periods of historical recruitment (beginning in 1940 or 1960). For each simulation year, in each set of 1,000 runs, the ratio of current biomass to virgin biomass was calculated and compared with the management objective of not exceeding 50% of virgin biomass within 50 y of harvest. An exploitation rate of 1.2% and 1.8% of estimated current biomass is recommended for the west coast of Vancouver Island and the rest of the coast respectively.

KEY WORDS: geoduck, *Panopea abrupta*, age, modeling, simulation, harvest rate, recruitment

INTRODUCTION

Geoduck, *Panopea abrupta* (Conrad, 1849), are large hiatellid bivalves that thrive in unconsolidated substrates in the northern Pacific from California to southern Japan (Coan et al. 2000). The clams are extremely long-lived, with a maximum-recorded age of 168 y (Bureau et al. 2002). They are slow growing after an initial phase of fast growth during the first 10 y of life, and growth rate and maximum size varies along environmental gradients and between geographic regions (Hoffmann et al. 2000, Bureau et al. 2002). Geoducks start to reach sexual maturity at age 2–3 y (Campbell & Ming 2003). Reproduction is through broadcast spawning during early summer months, followed by pelagic larval stage lasting 40–50 days (Goodwin et al. 1979, Goodwin & Shaul 1984). Postlarvae settle and move on the seafloor surface for several weeks (King 1986) until metamorphosis and the start of suspension feeding. The animals begin to dig and reach their final refuge depth of up to 1 m in approximately 4–5 y, after which predation mortality is extremely low. An exception to low mortality is in regions where the sea otter (*Enhydra lutris*) populations are recovering.

Geoducks are aggregated into beds, by virtue of their substrate requirements, and are thus structured as metapopulations with segments being interconnected through the flow of planktonic larvae. No evidence has been found of a relationship between the reproductive capacity of a population within a given location and subsequent recruitment to that location. Recruitment mechanisms operate differently during the periods of pre settlement and post settlement of larvae, and Orensanz et al. (2004) warn that key processes in the population dynamics may be completely blurred if analyzed at the wrong spatial scale.

Geoduck populations support lucrative dive fisheries in Washington State and British Columbia (BC), with an average annual landed value of 38 million Canadian dollars over the last five years in BC. The BC fishery is managed through a combination of limited entry and individual quotas (Heizer 2000). Annual quotas

are set at 1% of estimated virgin biomass, the harvest rate being a result of initial yield models that were based on intuition and the limited biological information available at an early stage of fishery development. To date, virgin biomass has been estimated by adding fishery removals to the estimate of current biomass from transect surveys, while natural mortality and recruitment are assumed to be equal. In contrast, the harvest rate in Washington is set to be 2.7% of current biomass based on the $F_{40\%}$ criterion (Bradbury & Tagart 2000).

The availability of a substantial accumulation of biological information warrants a new assessment of the geoduck stocks and re-evaluation of harvest rates in BC. Fishery-independent transect surveys have been conducted over all regions of the BC coast and, to date, include about 40% of the total estimated area of geoduck beds. Geoduck abundance, distribution and age composition have been collected from each surveyed location. Some important biological parameters of geoduck populations, such as growth and natural mortality rates, have also been estimated (Bureau et al. 2002, Zhang & Campbell 2004). In this paper, we study historic recruitment patterns through back-calculation, and investigate the impacts of alternative exploitation intensities on the geoduck populations through age-structured projection modeling.

MATERIALS AND METHODS

We conducted this study using biological information obtained from fishery-independent surveys and sampling, and fishery data obtained from logbooks. We back-calculated historic recruitment patterns using an age-structured model, and simulated future recruitment from the estimated historic recruitment pattern. The accuracy of the simulations was examined by comparing projected abundances with observed ones in four instances where repeat survey data were available. Through forward simulation, we evaluated the impacts of alternative fishing intensities on the stocks. Data were analyzed by survey bed and the results grouped by geographic region. In this paper, we divide the BC coast into five geographic regions: North Coast (NC), Central Coast (CC), Queen Charlotte Islands (QCI), West Coast of Vancouver Island (WCVI)

and Georgia Basin (GB) (Fig. 1). In this study, CC also includes two surveyed locations in Queen Charlotte Strait.

Fishery-independent Surveys

Each year, a number of geoduck beds are selected for surveying. Beds are chosen for various reasons, including significant contributions to total landings in the fishery, disagreement in the recommended quota for a bed or conservation concerns. If the selected location is comprised of many smaller beds, as opposed to beds that occur on large banks, the aggregate is partitioned into strata. For each strata, transect locations are selected randomly, following protocols described in Campbell et al. (1998) and Babuin et al. (2006). A number of quadrats 2-m wide and 10-m long are set along each transect from 60 feet chart datum to the intertidal, and SCUBA divers count the number of geoduck within each. Where appropriate, data are poststratified for analysis, where individual transects are excluded if the substrate was not suitable. Mean geoduck density and associated standard error were estimated for each bed using the two-stage random design estimator with transects as the primary sampling units and quadrats as the secondary sampling units (Thompson 1992). Biological samples are collected from the surveyed populations, from which length, weight and age data are obtained (Bureau et al. 2002, 2003). Age is determined using the acetate peel method (Shaul & Goodwin 1982) and, in most cases, estimated geoduck ages are provided with a range of uncertainty. Subsamples of approximately 150 animals each are collected from randomly selected transects throughout the survey location and combined into one sample per location.

Density and biological information from 42 fishery-independent surveys was used in the modeling. The 42 surveys were conducted in 38 locations; 4 locations were surveyed in two different years (Table 1). The number of individual geoduck beds surveyed per location varies from 1 to 18 (Table 1). From each surveyed location, between 186 and 580 geoduck were sampled for age determination.

Estimation of Historical Recruitments

Recruitment age is defined to be six years, the age at which we assume geoducks to become fully vulnerable to harvesting (Campbell et al. 2004). Historical recruitment rates (number of recruits/ m^2) were back calculated for each survey location, using estimated geoduck density, the age structure of the bio-samples collected and fishery removals as inputs to the model. Estimated historic recruitment strength relies on the natural mortality rate, M , used in the back-calculation. M for geoduck populations appears to vary approximately between 0.01 and 0.04 (Breen & Shields 1983, Harbo et al. 1983, Sloan & Robinson 1984, Noakes & Campbell 1992, Bradbury & Tagart 2000). In a tagging experiment in Washington, M was estimated to be 0.016 with a standard error of 0.0046 (Bradbury et al. 2000). Using experimental data from WCVI, Zhang and Campbell (2004) estimated M to be 0.036 with a standard error of 0.003. These two estimates of M approximately cover the range of M found in the literature, and were used in this study to estimate historic recruitment patterns.

The youngest age considered in this paper is six years. The maximum age was set to be 80 y for the sampling year, and geoduck older than the maximum age were pooled to form a maximum-plus age group. The maximum age for previous years was one year younger than for the subsequent year. For instance, in the year prior to the sampling year, the maximum age was 79 y and geoduck older than age 79 were pooled into the 79 + age group. In the sampling year, the abundance of geoducks for each surveyed bed is calculated as the product of mean density and the bed area, and the total abundance for each surveyed location is simply the sum of abundances for all the surveyed beds in the location. For each location, abundance at each age during the sampling year was estimated as the product of the total geoduck abundance and the proportion of geoduck at that age in the bio-sample. Abundance of geoduck at age a in year y (earlier than the sampling year), $N_{y,a}$, was estimated as:

$$N_{y,a} = N_{y+1,a+1} \times \exp(M) + C_{y+1} \times P_{y+1,a+1} \quad (1)$$

where C_{y+1} is the catch in number of geoduck in year $y + 1$, and $P_{y+1,a+1}$ is the estimated proportion of geoduck at age $a + 1$ in year $y + 1$. Thus, the proportion-at-age in the bio-samples was carried backward in the retrospective analysis as the proportion at each age-class. Where commercial landings were only reported by weight, C_{y+1} was estimated by dividing the landed weight by the mean geoduck weight for the location. Mean weight for a bed is estimated from the landed weight and number of geoduck, where number is reported in logbooks, over the period 1997 to present. Mean weight estimates from nearby beds may be applied if no estimate for a given bed exists.

Annual recruitment rate for an individual surveyed location was expressed as recruitment density by dividing the estimated abundance of age-6 in each year by the summed area over all the surveyed beds. Annual recruitment rate for a geographic region was calculated as:

$$R_y = \frac{\sum_{\text{location}} N_{y,6}}{\sum_{\text{location}} A} \quad (2)$$

where $N_{y,6}$ represents the estimated abundance of age-6 geoducks in year y in a location, and A represents the summed area over all the surveyed beds in a location.

¹ Central Coast (CC), North Coast (NC), Queen Charlotte Island (QCI), Georgia Basin (GB), West Coast of Vancouver Island (WCVI).

² Biological sampling was completed one year after the transect survey, for logistical reasons.

³ Surveyed locations where geoduck populations have been impacted by sea otters.

To evaluate uncertainties in the estimation, 999 simulations were conducted. In each simulation, geoduck densities, natural mortality rates, and age compositions were regenerated, and the simulated data sets were used to estimate the recruitment patterns, as described above. Densities in the sampling year were randomly regenerated from a normal distribution with the mean and standard deviation estimated from survey results. The value of M was randomly regenerated from a normal distribution with the designated mean and standard error (0.016 ± 0.0046 or 0.036 ± 0.003). The starting age composition of the bio-samples was bootstrapped by resampling with replacement to produce a simulated sample of the same size. A further step incorporated the uncertainty in ageing;

the actual age for each sample was randomly generated from a normal distribution, with the estimated age as the mean and one half of the error-range as the standard deviation. To test the impact of ageing uncertainty on simulated biomass estimates, we compared the expected biomass at the end of the simulation years with and without this uncertainty.

Projection Simulations

We assume that recruitment in the future will reflect what has occurred in the past. We fitted the 1,000 back-calculated recruitment data to the gamma probability distribution for each surveyed location using the least square error method, and used the fitted

distribution to describe the likelihood of recruitment rates for the location. In each simulation year, the number of recruits was randomly generated from the gamma distribution. For each surveyed location, biomass was projected onwards for 50 y from the sampling year under a given exploitation rate (E), which varies from 0% to 4% with an interval of 0.5%. We examined the impact of alternative harvesting intensities on the surveyed stock biomass to find plausible and precautionary E 's for the fishery. Population abundance at age $a + 1$ in year $y + 1$ was estimated to be:

$$\begin{cases} N_{y+1,a+1} = N_{y,a} \times (1 - E) \times \exp(-M) & (a < 80) \\ N_{y+1,a+} = (N_{v,a} + N_{y,a+}) \times (1 - E) \exp(-M) & (a = 80) \end{cases} \quad (3)$$

We used the weight-age conversion equations, which were established for each surveyed location by Bureau et al. (2002, 2003), to convert abundance to biomass. For each simulation year, a performance index was calculated as the ratio of current biomass (B_c) to the virgin biomass (B_v), the latter being the back-calculated biomass in the year just before the beginning of the commercial fishery in the location. The performance index for each geographic region was calculated by dividing the sum of B_c by the sum of B_v over all the surveyed locations in the geographic region. Among the nine surveyed locations in WCVI, four have been affected by sea otter predation (Table 1). We therefore calculated the ratio of B_c to B_v by using only the five unaffected locations.

Four possible simulation schemes were considered: recruitment simulation year starts from either 1940 or 1960, and the mean value of M used in the simulation is either 0.016 or 0.036. The 4 simulation schemes are thus denoted as Y40M0.016, Y60M0.016, Y40M0.036 and Y60M0.036. In general, future recruitment is more optimistic when the recruitment simulation year starts in 1940 than in 1960 because estimated recruitment is high during the period 1940–1960.

To evaluate uncertainties in the estimation, 999 simulations were conducted. In each simulation, age composition of the bio-samples, geoduck density in the sampling year, and value of M were randomly regenerated as described in the previous section.

Comparison of Projected and Survey-Derived Geoduck Densities

Surveys were conducted in two different years in each of 4 locations: Goletas Channel, Winter Harbour, Mission Group and Comox Bar (Table 1). This provides an opportunity to examine the location of the observed mean density within the range of the

Figure 2. Estimated mean historic recruitment rates for the entire BC coast.

model-projected densities, which is helpful in selecting a percentile level for determining harvest rates. Except in Comox Bar, different sets of the geoduck beds were surveyed on the two occasions; we used only the data obtained from beds which were surveyed on both occasions. We used results from the first survey to predict geoduck densities in the year of second survey. In each of the simulation years, recruitment was randomly generated from the gamma distribution, as described earlier. Population abundance

at age $a + 1$ in year $y + 1$, $N_{y+1,a+1}$, was calculated by rearranging Eq. 1. To incorporate uncertainties in estimated parameter values, 999 simulations were conducted.

RESULTS

Historic Recruitment Pattern

Trends in recruitment over time are comparable, irrespective of the value of M used in the back-calculation (Fig. 2), whereas the magnitude of estimated historic recruitment rates are affected by the value of M . Recruitment rates in the past were estimated to be higher when M of 0.036 was applied compared with a value of 0.016 (Fig. 2). Recruitment seems to have fluctuated appreciably in the virgin state in years prior to 1975. Overall, recruitment in the BC coast increased from at least 1930, and reached the highest around 1950. It then decreased until the early 1960s, before it started to increase again. Recruitment reached another peak in the mid-1960s, and then declined until mid-1980s. Recruitment has been increasing since the mid-1980s. In general, recruitment rates in 1940 to 1960 constituted the highest peak, and recruitment rates in 1960 to 1975 constituted a second, lower, peak. With application of M of 0.016, recruitment rates in recent years seem to be as high as in the highest historic period of 1940–1960. With application of M of 0.036, recruitment rates in recent years seem to be approaching the lower level in 1960–1975. The apparent decline in the most recent years is most likely because of under-sampling of young geoduck in the bio-samples.

Among the five geographic regions, average recruitment rates are the highest in the North Coast (NC) and Central Coast (CC), intermediate in Queen Charlotte Islands (QCI) and West Coast Vancouver Island (WCVI), and the lowest in Georgia Basin (GB) (Fig. 3). Recruitment patterns in NC, CC and QCI generally conform to the overall pattern for the entire coast whereas recruitment patterns in WCVI and GB lack the highest peak around 1950 (Fig. 3). Recruitment rates in GB in recent years appear to be the highest for the period studied.

Despite apparent differences in the overall mean recruitment rates between most geographic regions, ranges of mean recruitment rates (extent of minimum and maximum mean recruitment rates) over individual locations within a region are wide, and there are substantial amounts of overlap in these mean recruitment rates (Fig. 4).

Projection Simulations

For a given exploitation rate, stock biomass generally declines more quickly or increases more slowly, when the recruitment simulation starting year is 1960 rather than 1940, and/or when M

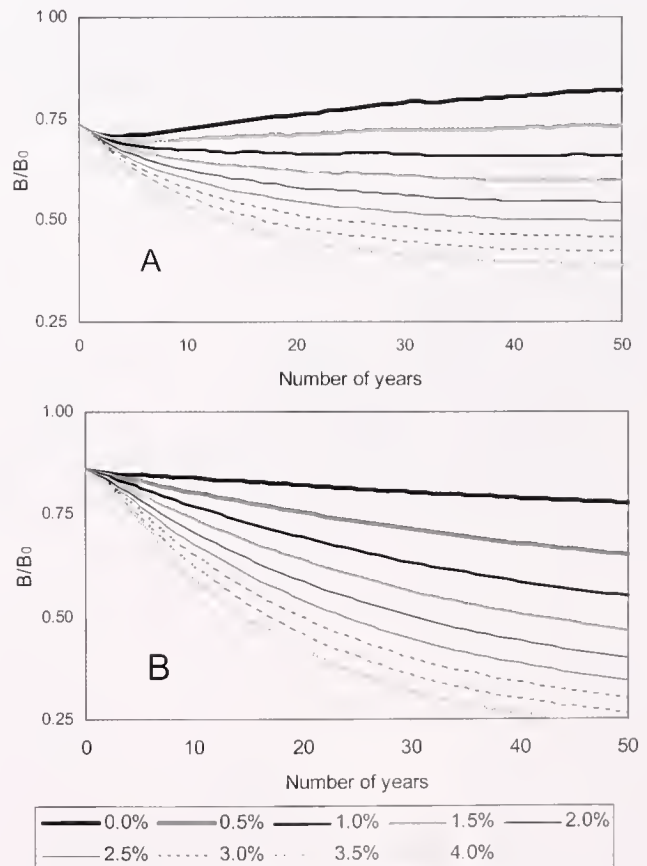

Figure 5. Simulated changes in the ratio of current biomass (B) to the virgin biomass (B_0) in the North Coast at the 50th percentile with different exploitation rates. (A: Recruitment simulation starting year is 1940 and M is 0.036. Note that biomass would decline to 50% of the virgin biomass with an exploitation rate of 2.5%. B: Recruitment simulation starting year is 1960 and M is 0.016. Note that biomass would decline even without harvesting).

used in the modeling is 0.036 rather than 0.016. All projection results are presented in Table 2.

With Y40M0.036, the geoduck stocks in NC could be harvested at 2.5% to have a 50% calculated chance of achieving the management goal of maintaining the biomass above one-half of the virgin biomass at the end of 50 y (Fig. 5A). E would be reduced to 1.7% if we want to raise the chance of achieving the goal to 90%. For the other four geographic regions, E could be set between 2.6% and 3.6% to have a 50% calculated chance of achieving the management goal, and would be reduced to 2.0% to 3.0%, if we want to increase the chance to 90% (Table 2). With Y60M0.036, the population would decrease in NC, CC, and QCI even without exploitation, because recruitment would not be sufficient to compensate for the loss caused by natural mortality. The geoduck stocks on WCVI could be harvested at 1.7% to have a 50% calculated chance of achieving the management goal of maintaining the biomass above one-half of the virgin biomass at the end of 50 y. E would be reduced to 1.1% if we want to raise the chance of achieving the goal to 90%. When we consider only the areas without sea otter predation, the corresponding E 's would be 1.9% and 1.2%. The geoduck stocks in GB could be harvested at 2.7% to have a 50% calculated chance of achieving the management goal, and 2.0% if we want to raise the chance to 90%. With Y40M0.016, E could be set to 2.4% to 3.6% for NC, CC, QCI and WCVI to have a 50% calculated chance of achieving the management goal and would be reduced to 2.0% to 3.0% if we want the calculated chance to increase to 90%. Stocks in GB again seem to be able to sustain higher harvest rates at 4.0%

and 3.7% for 50% and 10% percentiles, respectively. With Y60M0.016, recruitment would not be sufficient to compensate for the loss caused by natural mortality in NC (Fig. 5B), although it would take 50 y to reduce the biomass to one-half of the virgin biomass at a harvest rate of 1.3% (Table 2). E could be set at 1.8% to 3.5% to have a 50% calculated chance to achieve the management goal for CC, QCI, and WCVI and would be reduced to 1.6% to 2.8%, if we want to increase the chance to 90%. Geoduck stocks in GB seem to be able to sustain an exploitation rate around 4.0%.

Incorporation of uncertainty in geoduck ageing into the simulations produced slightly lower biomass estimates at the end of 50 y. The ratio of projected biomass to virgin biomass is, on average, 2.3% and 2.4% lower at the 50th and 10th percentile levels, respectively.

Comparisons of Recruitment Rates and Projected Densities

Recruitment densities estimated from the two independent surveys conducted in four locations agree with each other reasonably well (Fig. 6). Ninety-five percent, 82%, 92% and 87% of mean recruitment rates estimated from the second survey are located within the 95% confidence bounds based on the first survey for Goletas Channel, Winter Harbour, Mission Group and Comox Bar, respectively.

In Goletas Channel and Winter Harbour, the mean densities derived from the second surveys are either well within the interval of 10th to 90th percentiles or close to the 10th percentiles of

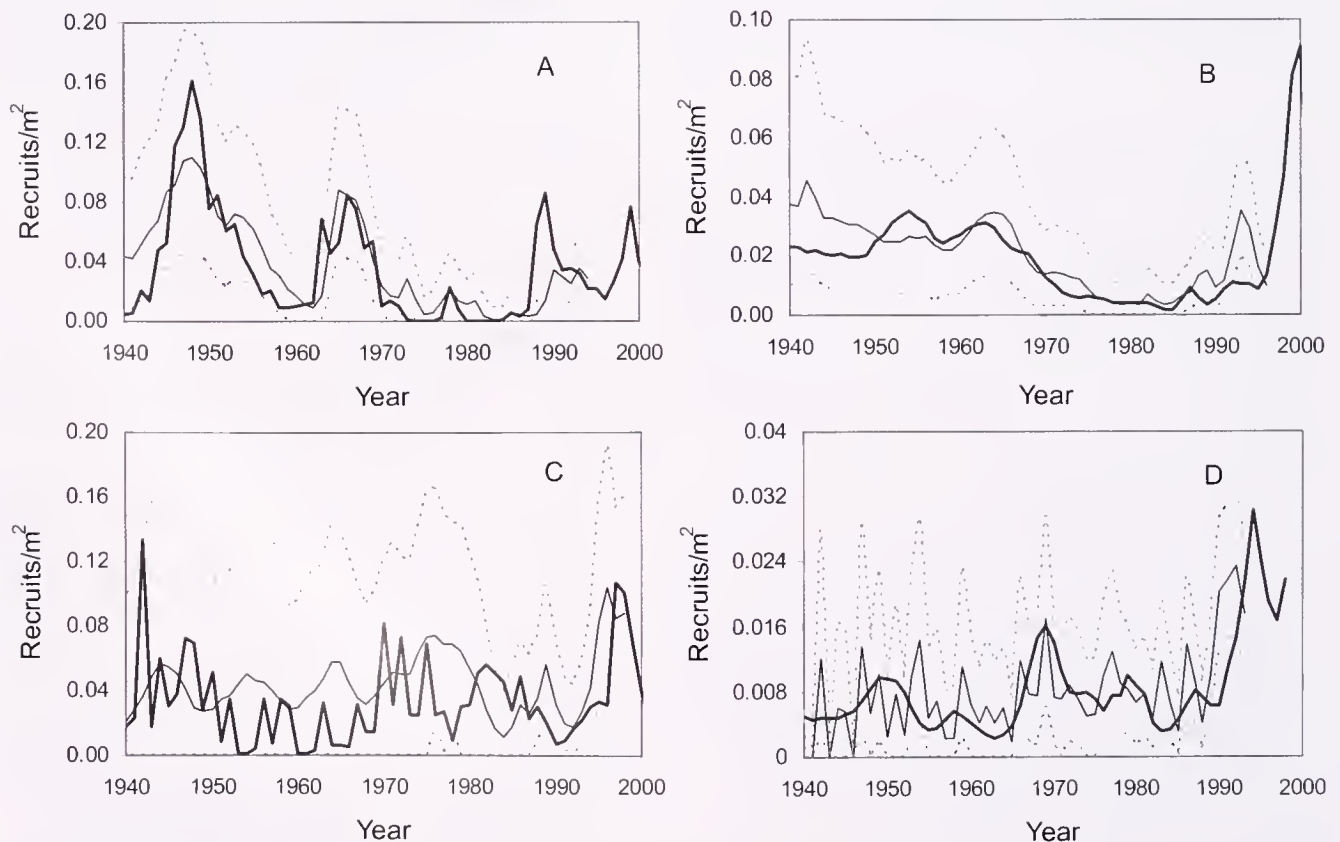

Figure 6. Comparison of recruitment density estimated from two surveys in different years ($M = 0.016$). The solid line represents the mean estimate based on the first survey, and the broken lines denote the 95% confidence limits. The bold line represents the mean estimate based on the second survey. (A, Goletas Channel; B, Winter Harbour; C, Mission Group; D, Comox Bar).

projected densities based on the first survey (Fig. 7A, B). In Mission Group, the observed mean density from the second survey is considerably lower than the 10th percentiles (Fig. 7C), probably because a substantial amount of geoduck were consumed by sea otters. Sea otters are also known to reside in Winter Harbour, but their impact on geoduck appears to have been considerably less severe (DFO, unpublished data). In Comox Bar, the mean density derived from the second survey is close to or above the 90th percentiles (Fig. 7D), which is consistent with the particularly strong recruitment observed in GB in the 1990s (Fig. 3). Because recruitment simulation relies on estimated recruitment in the past, the model is incapable of accurately projecting the abundance or biomass trends when there is a persistence of especially high or low recruitment.

DISCUSSION

This study provides a revealing glimpse at historic recruitment trends for geoduck populations in BC, and presents a method of evaluating impacts of alternative harvesting intensities on the geoduck stocks. Features related to the study and implications of our findings to the assessment and management of the geoduck fishery are discussed.

Geoduck stocks form metapopulations. There is virtually no stock-recruitment relationship in the traditional sense, because recruitment to one location is unlikely associated with the reproductive capacity in the same location (Orensanz et al. 2004). Compensatory or depensatory density-dependent processes were not explicitly incorporated into the analyses because there is no clear evidence of these mechanisms having an impact on recruitment,

survival and growth (Orensanz et al. 2004). Unless and until we could model the larval movement, we are not able to link recruitment in one spot to stock biomass in another. We are also currently unable to predict future recruitment rates based on environmental factors, although it is recognized that recruitment is likely related to the geographic and oceanic features in the immediate area. For instance, recruitment is higher in locations where water currents are of medium velocity (Goodwin 1990, Bureau et al. 2002). To conduct the recruitment simulations, we follow the advice of Maunder and Driso (2003) and assume that future recruitment will occur with a similar distribution as historical recruitment. Positive relationships between model-projected and observed abundances suggest that this approach is reasonable for geoduck populations in the absence of extraordinary recruitment or predation events.

Our estimated recruitment patterns for the five geographic regions generally agree with those reported by (Orensanz et al. 2004). Recruitment appears to have been strong in recent years throughout the BC coast, likely because of some favorable environmental conditions prevailing in these years (Valero et al. 2004). Overall historic recruitment trends appear to be similar for NC, CC, QCI, and, to a large extent, WCVI and GB as well, suggesting that geoduck recruitment may be regulated by common oceanic factors. However, within each geographic region, recruitment variation is large, which may preclude using regional index sites to represent recruitment trends in any given area.

Geoduck are long-lived animals, and natural mortality for geoduck populations must, therefore, be low. M has been estimated in the approximate range of 0.01–0.04 (Bradbury & Tagart 2000, Breen & Shields 1983, Noakes & Campbell 1992, Orensanz et al.

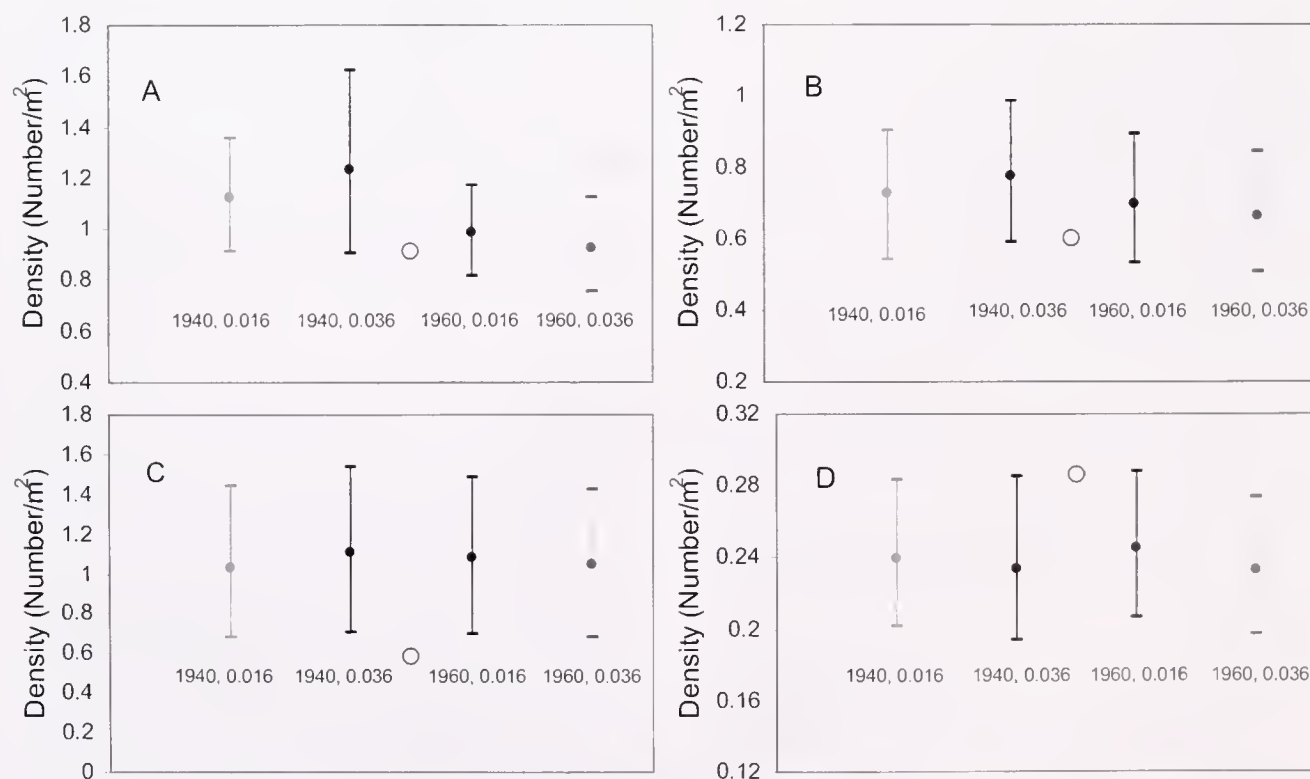

Figure 7. Comparison of projected and survey-derived geoduck densities. The solid dots represent the predicted median densities and the two bars represent 10th and 90th percentiles. The hollow circles denote the mean densities derived from the 2nd survey. Each set of two numbers indicates the starting recruitment simulation year and natural mortality rate used in the modeling. (A, Goletas Channel; B, Winter Harbour; C, Mission Group; D, Comox Bar).

2004, Zhang & Campbell 2004). We chose to use a small value of M (0.016) and a large value of M (0.036) in the simulation model to evaluate impacts of fishing intensities on the stocks. As actual M is likely to vary between the two values, the real impact of fishing intensities on stocks is likely to be between the two estimated extremes. Thus, choosing the more conservative exploitation rate from within the range provides for precautionary management. There is reason, however, to regard 0.036 as a more realistic average for geoducks than 0.016, which may to some degree underestimate the true lower range for M . The lower estimate came from a single tagging experiment on large, visible-siphon adult animals and might represent M for a lower-mortality portion of the population. In contrast, the higher estimate of M was developed using back-calculated age data over different sites and years, and therefore represents more than a single year of natural mortality and more than one population.

The productivity of a geoduck population is regulated by the balance of recruitment and growth on one side and natural mortality on the other. The rate of change in the ratio of current biomass to the virgin biomass depends on the productivity. The simulation model generates a wide range of exploitation rates over the simulation schemes, each rate having an associated calculated risk of failing the management goal. The comparison of model-projected and survey-derived densities in locations that were surveyed on two separate occasions indicates that the 10th percentile is a precautionary choice and more appropriate than the mean or median exploitation rates.

Simulation schemes that would cause the population abundance to decrease even without harvesting were considered to be unrealistic, particularly in areas where predation by sea otters has not been reported. Whereas some geoduck populations may decrease naturally in the short to medium term, particularly in areas that receive infrequent recruitment, modeling scenarios that lead to long-term stock collapse in the absence of harvest are not considered practical for commercial fishery management and are not considered further. The most conservative exploitation rates were generated from Y40M0.036 for the North Coast, from Y60M0.016 for Central Coast and Queen Charlotte Islands, and Y60M0.036 for West Coast Vancouver Island and Georgia Basin. Based on these precautionary simulation schemes, exploitation rates would be 1.7%, 1.8%, 1.6%, 1.2% and 2.0% for NC, CC, QCI, WCVI and GB, respectively. The proposed harvest rates for geoduck populations in BC are lower than the rate of 2.7% applied in the State of Washington, which was calculated based on the $F_{40\%}$ criterion (Bradbury & Tagart 2000).

ACKNOWLEDGMENTS

The authors thank the Underwater Harvesters Association, for providing funds to hire two students to assist us in this project; and Dominique Bureau, for his help in the use of the geoduck database and his constructive and valuable suggestions in our discussions; Ian Murfitt, for producing the map of the BC coast and the anonymous reviewer for valuable comments.

DIFFERENCES OF TURKISH CLAM (*RUDITAPES DECUSSATES*) AND MANILA CLAM (*RUDITAPES PHILIPPINARUM*) ACCORDING TO THEIR PROXIMATE COMPOSITION AND HEAVY METAL CONTENTS

T. DINCER*

Ege University Faculty of Fisheries Department of Processing Technology, 35100 Bornova-Izmir, Turkey

ABSTRACT The aim of this study is to determine the proximate composition, biometrical measurements and heavy metal content differences of marine bivalve *Ruditapes philippinarum* (Venice, Italy) and *Ruditapes philippinarum* (Izmir, Turkey). No statistical ($P < 0.05$) difference was observed in the values of crude lipid, moisture, ash and carbohydrate but statistical differences occurred in their crude protein values. They were $0.98 \pm 0.169\%$; $83.98 \pm 0.16\%$; $3.3 \pm 0.424\%$; $1.14 \pm 0.02\%$; $9.56 \pm 0.06\%$ for *Ruditapes decussatus*, respectively. They were $0.78 \pm 0.16\%$; $85.91 \pm 1.22\%$; $3.1 \pm 0.232\%$; $1.10 \pm 0.02\%$; $8.71 \pm 0.18\%$, for *Ruditapes philippinarum*, respectively. Each of the clam was determined as fresh and in perfect quality according to their TVB-N values but in the comparison of color values statistical difference was observed ($P > 0.05$). Trace metal levels were below the legal limits set by national standards of Turkish governments.

KEY WORDS: clam, color value, proximate composition, *Ruditapes*, measurements, heavy metals

INTRODUCTION

Water pollution has increased in heavy industrialized areas. Most industrial water wastes end up in the sea. Monitoring the elemental composition in marine organisms, such as clams, provides the essential elements in living organisms and through the food chain to humans. Bivalves can accumulate microorganisms, including pathogenic bacteria and viruses, when grown in polluted waters and can present a significant health risk when consumed raw or lightly cooked (West & Coleman 1986, Rippey 1994, Sobsey & Jaykus 1999, Croci et al. 2002, Formiga-Cruz et al. 2003). Pathogenic bacteria, such as *Salmonella typhi*, *Vibrio parahaemolyticus* and *V. cholera* remain viable for weeks in the marine environment, whereas viruses can survive for months in the same environment as well as in fish tissue. Some viruses, for example, the infectious hepatitis A virus, which has caused many shellfish associated outbreaks, can survive in seawater for more than a year and is frequently transmitted by shellfish consumption (Le Guyader et al. 2000, Muniain-Mujika et al. 2000, Romalde et al. 2002). One strategy that has been developed for bivalve risk management is utilizing their capacity to eliminate harmful microorganisms and toxic substances when held in clean, disinfected seawater tanks for up to 72 h (Roderick & Schneider 1994, Wong et al. 1997, Sobsey & Jaykus 1999). A number of factors are believed to be important in establishing effective purification; like design, initial water quality, oxygenation and flow rates, salinity, temperature, shellfish to water ratios, removal and settlement of fecal material and the period of purification (De Mesquita et al. 1991, Lee & Younger 2002).

The development of the commercial fishery for the littoral burrowing clams *Ruditapes decussatus* and *Ruditapes philippinarum* are based mainly on the export of live products to Europe (Le Borgne 1996). The shelf life (survival and palatability) of this product depends on a number of factors including postharvest storage time and temperature. There are obvious advantages in being able to prolong shelf life without affecting the sensory quality adversely, and achievement of this requires an assessment of

the biochemical and physiological responses of the clams to anoxia/temperature combinations.

Total aquaculture production of bivalves in the world is 37,851,356 tons, this production value consist of 370,631 tons mussel, 4,207,818 tons oyster, 1,219,127 tons scallop and pecten and 3,109,024 tons clams. Total fisheries production of bivalves is 92,356,034 tons in the world, 257,315 of total production come from mussel, 199,015 tons come from oyster and scallop, 702,525 tons come from pecten and 808,945 tons come from clams (FAO, 2001).

Total fishery production of bivalves in Turkey is 624,847 tons, of which 5,000 tons come from mussel, 10,000 tons come from clam and 70 tons come from oyster. And also 2 tons of mussels come from aquaculture production (Anonymous 2002). The first exportation of the bivalves to Europe began in 1970 with clam *Ruditapes decussatus*. The most important species exported to foreign countries from Turkey are *Mytilus galloprovincialis*, *Ruditapes decussatus*, *Venus verrucosa*, *Ostrea edulis*, *Venus gallina* and *Arca sp.*

Several recent studies highlight the importance of using an integrated approach to assess environmental quality and effects of toxicants on organisms (Den Besten 1998, Livingstone et al. 1995, Mc Carthy & Shugart 1990). Differences in natural variables (i.e., sample site, exposure duration, population variation, temperature, salinity, etc.) complicate the identification of any biological responses to toxic substances. Transplantation of bivalve samples from a population at one location to other sites reduces the variability of results usually encountered in field sampling programs (De Koek & Kramer 1994, Amiard et al. 1987). Usero et al. (1997) studied trace metals in the bivalve mollusks *Ruditapes decussatus* and *Ruditapes philippinarum* from the Atlantic coast of southern Spain. Accumulation of metals, especially nonessential ones, is greatly dependent on their concentration in ambient water (Phillips & Rainbow 1989, Amiard et al. 1987) although there are other factors that affect accumulations such as the organism's size (Ringwood 1993, Brix & Lyngby 1985, Strong & Luoma 1981) and reproductive state (Paez-Osuna et al. 1995, Bordin et al. 1992). Concentrations of trace metals in *R. decussatus* and *R. philippinarum* reported in the study (Usero et al. 1997) were comparable to published data from less extensive surveys on the Southern Atlan-

tic Coast of Spain (AMA 1992). Tuncer and Uysal (1982) found higher concentrations of Mn, Cr, Pb and similar concentrations for the other metals analyzed in *R. decussatus* in Izmir Bay (Turkey).

Bivalve mollusks have frequently been used as bioindicators for monitoring heavy-metal pollution because they are filter-feeding organisms with limited mobility (Storelli & Marcotrigiano 2001). The clams *Ruditapes decussatus* and *Ruditapes phillipinarum* were evaluated as possible biomonitors for Izmir bay and Venice bay. In this aim determining the differences of proximate and heavy metal contents is important.

MATERIALS AND METHODS

R. decussatus samples were taken alive from an aquaculture foundation, which was located in the province of Izmir city in Turkey, and the *R. phillipinarum* samples were taken alive from the fish market in Hamburg, in Germany. *Ruditapes phillipinarum* samples were imported from Venice, Italy. Analytical analysis of *Ruditapes decussatus* were performed in Turkey, on the other hand *Ruditapes phillipinarum* samples were analyzed in Federal Research center for fisheries, in Hamburg, Germany.

Biometric Measurements

Clams were immediately transported to the laboratory, where the fresh weights and linear dimensions (length, height and width) were determined. Clams were then opened, damp dried, soft tissues removed and shell and soft tissues weighed.

Proximate Composition

Proximate composition analysis of moisture (Ludorff & Meyer 1973), crude fat (Bligh & Dyer 1959) and crude protein (AOAC 1984) of *Ruditapes decussatus*, were performed and determined. Total volatile basic nitrogen (TVB-N) analysis was performed by using Kjeldhal Vapo 40 (Antonacopoulos & Vyncke 1989). Made in Turkey.

Proximate composition analysis of moisture (Oehlenschläger 1986), crude fat (Oehlenschläger 1986) and crude protein (Oehlenschläger 1997) of *Ruditapes phillipinarum* were performed and determined. TVB-N (Total Volatile Basic Nitrogen) analysis was performed by using Kjeldhal Vapo 50 (Rehbein et al. 1994). Made in Germany.

For proximate analyses and TVB-N analyses clam samples were pooled and homogenized. The analyses of the pooled samples were all carried out in triplicate.

Color Measurement

Instrument

The color measurement on samples trials was carried out with the spectral color meter Spectro-pen (Dr. Lange, Dusseldorf, Ger-

many). This is a colorimeter operating on the spectral method described in DIN 5033 using the 45/0° circular viewing geometry. The sample is illuminated with polychromatic light encircling it at an angle of 45°, with the optical unit observing the reflected light from a horizontal angle (0°) towards the sample surface. Spectro-pen is a genuine grating colorimeter measuring the visible spectral range (400–700 nm) at intervals of 10 nm. A 10° standard observers and D65 illuminant were used (light source: polychromatic with tungsten lamp). The PC software "spectral—QC" allows state-of-the-art data processing. Before measuring each lot, the colorimeter was calibrated against a white standard (LZM 224).

Measurement

The color measurement of clam samples trials was carried out with the spectral color meter Spectro-pen (Dr. Lange, Dusseldorf, Germany). The color was measured on homogenates prepared from each fish. The homogenate was placed in plastic petri dishes and the color measurement was repeated 10 times. In the CIE Laboratory system L*denotes lightness on a 0–100 scale from black to white; a*, (+) red or (–) green; and b*, (+) yellow or (–) blue (Schubring & Meyer 2002).

Concentration of Trace Metals

Purpose of this study was to obtain quantitative information on the concentration of trace metals in two bivalve species from Izmir outer Bay and Venice, which samples were taken from the fish market in Hamburg, in Germany (Origin, Venice Italy).

The following points were considered: variations of metal concentrations among two species, variations of metal levels and the relationship between metal content and bivalve size. All samples were lyophilized in a FinnAqua Lyovac GT 2 freeze dryer (parameters: ambient temperature –20°C, vacuum 5–10 Pa, duration at least 48 h) and finally finely milled in a ball mill made from agate (Planetary Ball Mill, Fritsch, pulverisette 5, Idar-Oberstein, Germany). After milling, all samples were kept in high-density polyethylene bags at room temperature in an exsiccator until mineralization. Lyophilized samples (approximately 0.5 g) were weighed into petri dishes, which were put in a closed low-

temperature microwave activated oxygen plasma processor (Plasma Processor 200-G, Techniques Plasma, Munchen, Germany) for mineralization (power supply 350–360 W, vacuum 60–90 Pa, oxygen partial pressure 2.0–2.5_105 Pa); the duration of decomposition was 144–168 h. The decomposed samples were quantitatively transferred into 100-ml volumetric flasks and dissolved in supra pure H₂SO₄ (0.2%, w/w) at pH 2., DPSAV (746 VA Trace Analyzer, Metrohm, Switzerland) equipped with auto sampler (695 VA Auto sampler, Metrohm) and was used for the determination of heavy metals.

Statistical Analysis

SPSS 9.1 for windows program was used to search for significant differences between mean values of the different results. Differences between means were analyzed by 1-way analysis of variance (ANOVA) followed by Tukey and Duncan tests. Results are presented as means ± SD ($n = 3$ or 4).

RESULTS

The crude protein, total lipids, moisture, ash and carbohydrate contents of the clams are shown in Table 1.

According to their proximate composition data statistical difference occurred only in crude protein values. No statistical ($P < 0.05$) difference was observed in the values of crude lipid, moisture, ash and carbohydrate. They were $0.98 \pm 0.169\%$; $83.98 \pm 0.16\%$; $3.3 \pm 0.424\%$; $1.14 \pm 0.02\%$; $9.56 \pm 0.06\%$ for *Ruditapes decussatus*, respectively and $0.78 \pm 0.16\%$; $85.91 \pm 1.22\%$; $3.1 \pm 0.232\%$; $1.10 \pm 0.02\%$; $8.71 \pm 0.18\%$, for *Ruditapes philippinarum*, respectively. Protein content of *Ruditapes philippinarum* was higher than *Ruditapes decussatus*.

The TVB-N and pH values of the raw material are shown in Table 2.

In seafood, total volatile basic nitrogen (TVB-N) primarily includes trimethylamine (TMA), ammonia and dimethylamine (DMA). Each of these compounds, as well as total levels of TVB-

N, are useful indices of spoilage in different fresh and lightly preserved seafood. The European Commission (E.C. 1995) specified TVB-N to be used if sensory evaluation indicates doubt about freshness of different fish species. Critical limits of 25, 30 and 35 mg-TVb-N/100g were established for different groups of fish species. In processed, lightly or semi preserved, seafood levels of TVB-N at sensory product rejection are more variable. There was a significant difference between two data but this difference did not mean that those raw materials were not fresh. Total volatile basic nitrogen (TVB-N) includes all volatile amines. TVB-N is a spoilage index for fish and shellfish (FAO 1986). It is indicated that samples including lower than 25 mg N/100 g TVB-N value are in "perfect quality," samples including 30 mg N/100 g TVB-N value are in "good quality," samples including 35 mg N/100g TVB-N are in 'marketable quality' and the samples including more than 35 mg N/100 g TVB-n value are indicated as "spoiled" (Schormuller 1968, Ludorf & Meyer 1973). No statistical ($P < 0.05$) difference was observed in the values of pH.

The biometrical measurements of the clams are shown in Table 3.

According to their biometrical measurements *Ruditapes philippinarum* had mostly higher values than *Ruditapes decussatus* except one criterion, which was the length. These results showed us that *R. philippinarum* is a little bit bigger than *R. decussatus*.

The color measurement data of the clams are shown in Table 4.

Their color data were very different as shown in the Table 4. *R. philippinarum* was much lighter, much redder and much yellower.

The two bivalves accumulated different amounts of metals in their tissues. Analysis of variance showed that the concentrations of zinc, cadmium, lead, copper and arsenic were significantly higher in *R. philippinarum* than in *R. decussatus*. Usero et al. (1997) found lower concentrations of zinc, cadmium, lead, copper and similar concentrations for the other metals analyzed in *R. decussatus* in Izmir Bay (Turkey).

Lead is considered to be a toxic element as a consequence of a variety of biochemical effects. These include neurological problems, hematological effects, renal dysfunction, hypertension and cancer, for which there is evidence for animals but not yet for humans. The maximum heavy metal levels permitted in Turkey are 0.1 mg/kg for cadmium and 1.0 mg/kg for lead according to the Turkish Food Codex (1997). So all the values are reasonable for human life according to Turkish Food codex.

CONCLUSION

In this study proximate composition and biometrical size of two clams was compared. These clams were all of commercial value in the seafood industry. The aim of this study was determining the differences of these two species. Although there are some differ-

<i>Ruditapes decussatus</i>	22 ± 17	250 ± 006	370 ± 0.05	3.4 ± 0.36

(Mean ± standard deviation)

ences, these differences do not mean that the Turkish clam would not be alternative specie for the seafood industry. And also according to their trace metal contents all the values are under the limits of consumption according to Turkish food codex. Although

fishery activity and the culture of this species has some difficulties, with the support of new scientific investigations and the commercial support of the foundations, this clam could become a real alternative choice to the European species on an industrial scale.

BIOTIC AND ABIOTIC FACTORS INFLUENCING GROWTH AND SURVIVAL OF WILD AND CULTURED INDIVIDUALS OF THE SOFTSHELL CLAM (*MYA ARENARIA* L.) IN EASTERN MAINE

BRIAN F. BEAL*

University of Maine at Machias, 9 O'Brien Avenue, Machias, Maine 04654

ABSTRACT A series of intertidal field experiments was conducted from 1986–2003 in eastern Maine to examine biotic and abiotic factors influencing the growth and survival of wild and cultured individuals of the softshell clam, *Mya arenaria* L. Separate experiments examined: (1) the efficacy of transferring sublegal wild clams (<50.8 mm SL) from areas near the high intertidal zone where shell growth was slow to areas where growth was predicted to be faster; (2) effects of tidal height on wild and cultured clam growth; (3) effects of spatial variation on cultured clam growth; (4) dispersion and growth of cultured juveniles in small experimental units; (5) effects of the naticid gastropod, *Euspira heros* Say, predation on survival of wild and cultured clams and (6) the species composition of large, crustacean predators that forage intertidally during periods of tidal inundation. Protective netting (4.2 mm aperture) increased recovery rate of transferred clams by 120% and resulted in a 3-fold enhancement of wild recruits. Effects of tidal height on wild clam growth revealed complex behaviors in >0 y-class individuals. Clams growing near the upper intertidal take >8 y to attain a legal size of 50.8 mm SL, whereas animals near the mid intertidal generally take 4.5–6.5 y. Unexpectedly, clams initially 38–54 mm SL and growing near the extreme low tide mark at a mud flat in Eastport, Maine, added, on average, <2 mm of new shell in a year, which was 8–10 mm SL less than animals at higher shore levels. It is hypothesized that biological disturbance by moon snails, that consumed >90% of clams at the low shore levels, contributed to this slow growth. In another field trial from 1986–1987, moon snails and other consumers were allowed access to clams ranging in size from 15–51 mm. *E. heros* preyed on clams over the entire size range and attacked clams between 31–40 mm at a rate that was nearly double what had been expected. Mean snail size was estimated to range from 10–52 mm shell height (SH), based on a laboratory study that yielded information about the linear relationship between snail size and its borehole diameter. In an experiment from June to September 1993, moon snails consumed >70% of juvenile clams (ca. 10 mm SL) within a month after planting at each of three tidal heights. Snail sizes ranged from 15–20 mm SD with larger individuals occurring near the upper intertidal zone. Green crabs, *Carcinus maenas* (L.) also prey heavily on softshell clam populations, but most studies that use shell damage to assign a predator have assumed that all crushing and chipping predation is because of this invasive species. An intertidal trapping study demonstrated that both green crabs and rock crabs, *Cancer irroratus* Say, are present during periods of tidal inundation, with the latter species accounting for ca. 40% of large crustacean numbers.

KEY WORDS: *Mya arenaria*, softshell clam, Maine, growth, predation, *Euspira heros*, *Carcinus maenas*

INTRODUCTION

In Maine, USA, softshell clams, *Mya arenaria* L., are the third most important commercial marine species harvested behind lobster, *Homarus americanus* Milne Edwards, and cultured salmon, *Salmo salar* L. From 2001–2004, dockside clam landings in Maine averaged ($\pm 95\%$ CI) 1113.9 ± 99.7 metric tons (worth $\$15.9 \pm \1.68 million; Fig. 1), worth more than \$50 million annually to the state economy (ME DMR 2005).

Each of Maine's 105 coastal communities has the option to manage its intertidal clam stocks within its municipality using one of the oldest comanagement programs in the United States. Beginning in 1962, Maine's State Legislature created a community-based management structure between municipalities and the State of Maine through the Department of Marine Resources (DMR). This structure, or agreement, is called a "shellfish ordinance," and it allows towns to adopt, amend or repeal a set of shellfish conservation measures that regulate the taking of shellfish within the intertidal zone of the municipality. The ordinance is a broadly defined document that includes language about conservation activities, qualifications of a licensee, license fees, limiting effort, harvesting methods and tools, enforcement, the organization and rights of a local stewardship committee and other measures. The first step a town must take once it declares its intention to manage its local clam assets is to adopt a "model ordinance," or general management plan, that outlines basic requirements the state man-

dates. (Towns not interested in managing their clam stocks are not required to do so, and, therefore, the State must act alone to manage those intertidal flats to the best of its ability.) However, the model ordinance is structured to permit sufficient flexibility to enable a community to benefit from local knowledge, wants and wishes by creating, adopting and regulating its unique management schemes that may exceed the basic provisions set out in the model ordinance. These local modifications are enacted when a community requests them in writing to the DMR, and they are granted by the DMR Commissioner. In this way, two adjacent communities may have a common goal of increasing local clam stocks, but have very different looking shellfish ordinances. There are 3 common requirements of all communities with shellfish ordinances: (1) the management plan be enforced by a warden paid through the town; (2) no clam less than two-inches (50.8 mm) in shell length (SL) can be harvested legally and (3) 10% of licenses sold in a community must be made available to Maine citizens outside the particular municipality. In 2005, 73 communities (or 70%) with intertidal habitat chose to manage those areas for *M. arenaria* production.

Since the inception of the shellfish ordinance, local stewardship committees have adopted a number of shellfish management tools in an attempt to maintain high yields of clams and keep their clamming habitat productive. The following list includes management activities that have been used in Maine since 1962—no community has adopted all of the activities: (1) limiting the number of licenses sold; (2) restricting harvest volumes; (3) limiting all harvesting to recreational diggers; (4) limiting when harvesting can

*Corresponding author: E-mail: bbeal@maine.edu

Figure 1. Commercial landings of softshell clams in Maine from 1950 to 2004. Data from: <http://www.maine.gov/dmr/commercialfishing/softshellclam.htm>.

occur (e.g., no Sunday digging; no night digging); (5) restricting the areas where harvesting can occur (i.e., flat rotations); (6) applying tree brush or snow-fencing to intertidal areas to encourage juvenile clams settlement; (7) applying wire fencing or plastic netting to deter green crab predation and encourage juvenile clam settlement; (8) assessing stock volume and size frequency distributions (i.e., clam surveys); (9) transferring clams from high density/slow growth areas to low density/fast growth areas; (10) enhancing flats with hatchery-reared, or cultured clam seed; (11) installing municipal sewage treatment systems and reducing over-board discharges (e.g., water quality monitoring programs) and (12) municipal leasing of flats (each community has the right to set aside up to 25% of its productive clamming habitat for private clam farming operations).

Shellfish committee members, in concert with State resource managers, must make decisions concerning the status and health of soft-shell clam populations for a variety of applications, the most common being whether the population is abundant enough to be harvested in a sustainable fashion and what level of harvesting will minimize impacts on future populations. Because of logistical constraints imposed by working in marine environments, managers of marine resources often have limited information about important population characteristics such as survival, growth and recruitment rate and how these parameters change spatially and temporally. Rather, decisions about harvest levels, for example, usually are limited to estimates of change in standing stocks and size frequencies through time or between locations.

It is rare that adaptive management strategies and experimental approaches are considered by fisheries managers (but see Botsford et al. 1997, Lenihan & Micheli 2000, Beal & Vencile 2001); however, manipulative field experiments are the strongest and most efficient means available to managers to base decisions about the dynamics of a population (Underwood 1990, Underwood 1991). The field trials reported here are intended to add to a growing literature on soft-shell clam ecology from Maine and western New Brunswick, Canada (Spear & Glude 1957, Welch 1969, Comito 1982a, Comito 1982b, Newell & Hidu 1982, Ambrose et al. 1998, Beal et al. 2001, Beal and Kraus 2002, Whitlow et al. 2003, Auffrey et al. 2004, Logan 2005) and provide information to shellfish stewardship committees and resource managers that increases the scope of their management toolbox.

This contribution summarizes a number of field investigations conducted in eastern Maine since 1986 that focuses specifically on

the biotic and abiotic factors affecting growth and survival of wild and cultured softshell clams.

METHODS

Experiment 1

Clam Transfers

In 2004, approximately 44% of the 73 Maine communities that actively managed their shellfish stocks participated in some form of transfer program (ME DMR 2005). These activities are very labor intensive because they involve harvesting and transporting wild "seed clams" from areas where growth is slow or retarded (i.e., near the upper intertidal where clam growth can be 95% slower than growth of the similar animals at the low intertidal [Beal et al., 2001]) to areas where growth is faster. Most communities transfer clam seed that is approximately 38–45 mm SL (pers. obs.). To the best of my knowledge, there has been only one attempt to quantify the efficacy of transfers in Maine. Here, information is presented that examines short-term survival, growth and recruitment patterns of transferred clams.

On May 2, 1998, approximately 165 kg of soft-shell "seed" clams were dug by commercial harvesters from the city of Eastport, Maine in the high intertidal zone of a flat near Carlow Island in Passamaquoddy Bay (44°56.34'N; 67°01.77'W). Animals were slow growing, and annual ring counts (Newcombe 1935) indicated that the oldest animals were >15 y old. Clams were sieved, washed, and stored overnight in a walk-in cooler at 4°C. A random sample of these clams ($n = 96$) demonstrated that the ranges of SL's varied from 23.2 mm to 58.5 mm with a mean SL = 39.3 ± 9.5 mm. A relationship between clam mass and clam number was developed for those clams by counting five separate lots of individuals at 0.45, 1.36, 2.27 and 3.18 kg (Count = $0.03 + 107.21 \times \text{Mass}$; $n = 20$; $r^2 = 0.969$; $P < 0.001$). This relationship was used to estimate number of clams seeded into plots (9.3 m^2) at a nearby intertidal flat, Carrying Place Cove, Eastport, Maine (44°54.04'N; 67°01.28'W), at low tide on 3 May 1998. Seeding densities were 0, 4.1, 6.1 and 12.3 kg per plot, or 0, 440, 654 and 1319 clams per plot representing approximately 0, 47, 70 and 142 animals m^{-2} .

Six treatments, with five replicate plots each, were established: (1) 0 kg with a piece of 4.2 mm flexible plastic netting to deter predators; (2) 4.1 kg with netting; (3) 4.1 kg with no netting and surface of flat roughened with clam harvesting hoes (*sensu* Robinson & Rowell 1990); (4) 6.1 kg with no netting; (5) 6.1 kg with 4.2 mm flexible plastic netting and (6) 12.3 kg with no netting. Treatments were randomly assigned to plots that were established in a 6×5 matrix with 5 m between rows and columns. An initial survey of the experimental area failed to locate a single living clam. To estimate the short-term effect of enhancing flats through transferring seed clams, each plot was randomly sampled twice on October 27, 1998 using a coring device (0.02 m^2) to a depth of 20 cm. All transferred clams per core sample were counted and the SL of each live clam was measured to the nearest 0.1 mm using Vernier calipers. It was possible to distinguish "new shell growth" as an obvious white band along the entire ventral margin of the clam.

Several *a priori* contrasts were of interest for both growth and survival variables: (1) Is netting important to retain transferred clams? This was tested by comparing treatments 4 & 5; (2) Does roughening the sediment surface enhance the burrowing rate of clams? This was tested by comparing treatments 2 & 3 and (3) Is

there an effect caused by seeding density? This was tested by comparing the mean of treatments 2 & 4 versus 6. In addition, the control plots (without seed) were used to compare recruitment of wild spat (animals <18 mm SL) in netted plots to similar plots containing transferred seed. This was a comparison of the mean of treatment 1 versus the mean of treatments 2 & 5. A conservative decision rule was used for each contrast based on advice from Winer et al. (1991) who cautioned against excessive type I error by reducing α using the following equation:

$$\alpha' = (1 - \alpha)^{1/m}$$

where m = the number of contrasts.

In this instance, because $m = 3$, α' equals 0.0170.

RESULTS

Survival

Between 30% and 70% of clams initially transferred were missing from plots at the end of the 5-mo experimental period. Greatest missing rates occurred in the low-density plots. Table 1 demonstrates that protecting clams with netting had no statistically significant effect on clam density after 5 mo ($P = 0.0293$); however, mean density under the netting was approximately twice that in plots without netting (220 ± 35.9 vs. 100.0 ± 36.5 animals m^{-2} ; $n = 5$). There was no significant difference in final density between roughened versus nonroughened plots (20.0 ± 14.5 vs. 15 ± 6.0 individuals m^{-2} , respectively). In addition, significant differences in final clam density were observed after 5 mo; however, instead of a 3-fold difference between highest and smallest density treatments that was incorporated into the experimental design (see earlier), a 5-fold difference in final density was observed (95.0 ± 24.0 vs. 17.5 ± 10.3 animals m^{-2} ; Table 1; $P = 0.0074$).

Growth

Clam growth was related to initial planting size (Fig. 2), but was unaffected by stocking density, netting and sediment roughening ($P > 0.80$). Clams initially <35 mm added, on average, 8.1 ± 1.14 mm ($n = 13$) of new shell between May and October 1998 compared with 3.4 ± 0.56 mm ($n = 27$) for animals >35 mm ($P = 0.0002$).

TABLE 1.

Analysis of variance on the square root-transformed number of re-seeded clams per 0.02 m^2 sample taken on October 27, 1998 at Carrying Place Cove, Eastport, Maine. Two random samples were taken from each of five replicates of each treatment ($2 \times 5 \times 5 = 50$ samples). A priori contrasts appear under the Treatment source of variation and a decision rule equal to $\alpha' = 0.0170$ was used.

Source of Variation	df	SS	MS	F	Pr > F
Treatment	4	10.84	2.71	11.87	0.0091

Figure 2. Absolute growth ($\pm 95\%$ confidence interval) of softshell clams transferred to Carrying Place Cove in Eastport, Maine from May 2 to October 27, 1998. $Y = 15.3 - 0.262 X$; $n = 40$; $r^2 = 0.368$; $P < 0.001$.

Recruitment

No wild spat were found in control plots that did not receive clam seed, nor were spat found in samples from the low density stocking treatment. ANOVA on the square root-transformed number of wild spat (<18 mm SL) per core (Table 2) demonstrated a significant effect because of the presence of the netting as 3.3 times as many spat were found in netted versus unnetted plots (50.0 ± 21.1 versus 15.0 ± 7.6 individuals m^{-2} ; $n = 5$). In addition, number of wild spat increased significantly with stocking density ($P = 0.0087$; Table 2) from 15 ± 7.2 – 45 ± 10.3 individuals m^{-2} ($n = 5$) in plots initially seeded at densities of 70, and 142 animals m^{-2} , respectively. No differences in SL were observed across the seeding treatments for the wild spat ($P = 0.8606$).

Experiment II

Growth of Soft-shell Clams in Eastern Maine

Clam growth rates vary geographically along the coast of Maine. Dow and Wallace (1953) reported that in some areas of eastern Maine, it takes an average of 8 y for *Mya* to reach legal size

TABLE 2.

Analysis of variance on the square root-transformed number of wild clam spat (0-year class individuals <18 mm SL) per 0.02 m^2 sample taken on October 27, 1998 at Carrying Place Cove, Eastport, Maine.

Two random samples were taken from each of five replicates of each treatment ($2 \times 6 \times 5 = 60$ samples). A priori contrasts appear under the Treatment source of variation and a decision rule equal to $\alpha' = 0.0170$ was used.

(50.8 mm SL). This average decreases in a southwesterly direction where, in the area from Portland to Kittery, it takes approximately 3 y for animals to attain legal size. In addition, tidal inundation may influence growth rates as clams cease growing during periods when the tide leaves the mudflats. To investigate how clam growth is influenced by tidal position, a number of studies have been carried out during the past decade in eastern Maine. Here, results from four investigations are presented that were conducted in Eastport, Jonesport, and Addison.

METHODS

Eastport

Twenty 0.25 m² plots (corners marked with wooden stakes) were established at Carrying Place Cove on April 22, 1998 at 10 separate locations ranging from extreme low tide (plots 1–3) to lower mid tide (plots 4–6) to upper mid tide (7–9) to upper tide (plot 10). At each location, replicate plots were established. Wild clams used in the study were dug on April 19, 1998 near Carlow Island (described in the **Clam Transfers** section) and ranged from 23.8–59.0 mm SL. Animals were held in a cold room at 4°C, and on April 21, approximately 170 clams were uniquely marked with an oil-based ink (Mark-Tex Corp.) and measured to the nearest 0.1 mm using Vernier calipers. To facilitate planting the clams and to aid in their burrowing, on April 22 the surface of each plot was roughened using a clam hoe. Then, 17 marked and 10 unmarked clams were pushed into the sediments (so that the posterior margin of each clam was 1 cm below the sediment) in one of the two plots (a) at each location 27 unmarked individuals similarly were planted in the other plot (b). Sediment type varied from location to location along the tidal gradient. Plots became sandier towards the mid-tide area (except for plot 7, which was located in a blue clay sediment). Plots 1–3 typically were exposed only briefly (ca. 30–40 min) on the spring tides of each month, and clam growth rate in these plots was predicted to be the fastest because these animals were able to feed longer each tidal cycle than clams in plots at the higher tidal levels. Conversely, growth rate of clams in plots at the uppermost tidal level was predicted to be the slowest because those plots were exposed daily for the most amount of time during each semidiurnal tidal cycle (ca. 240–300 min).

On April 20, 1999, all 20 plots were excavated and all live and dead animals were taken to the laboratory. Each live clam was examined for a disturbance line believed to coincide with the size of the clam on 22 April 1998 (see an example of this technique for juveniles of *M. arenaria* in Beal et al. 1999). The marked clams enabled me to test the hypothesis that the disturbance line coincided with the size of the animal when it was transferred to the 0.25 m² plot. Using calipers, the length of the marked animal at the disturbance line was estimated and recorded. This size is referred to as a "predicted length." After all marked animals from each plot had been measured, these predicted lengths were compared with the actual lengths that had been recorded the previous year. A perfect correlation would result in a line with the equation $Y = X$. A 2-tailed, one-sample *t*-test was performed to test whether the difference between actual and predicted was zero. Fifty-nine marked individuals (of 170) were found alive in all 10 locations. The mean difference between the actual length and the predicted length for these 59 clams was 0.098 mm (minimum difference was –0.5 mm and the maximum difference was 1.4 mm; Fig. 3). The test revealed that the mean difference was not significantly different from zero ($T = 1.836$; $df = 58$; $P = 0.072$), suggesting that

Figure 3. Predicted versus recorded shell length of marked clams from Carrying Place Cove, Eastport, Maine, on April 20, 1999. Predicted SL was based on an obvious disturbance mark in the valve of clams that had been marked with ink near their umbo on April 22, 1998. Because the equation of the line ($Y = -0.55 + 1.012 X$; $n = 40$; $r^2 = 0.998$) is not significantly different from $Y = X$, the disturbance line was used to establish the size of unmarked clams in the growth rate experiment.

the disturbance line on each valve coincided directly with the handling, planting and other disturbance the animals had endured a year earlier. Because clam growth over the entire year could be discerned, Ford-Walford plots (Walford 1946) were used and then converted to von Bertalanffy equations. These equations were plotted to generate plot- and tide-specific growth rate curves.

Jonesport

Hatchery-reared clams (12.4 mm \pm 0.31 mm), produced in 1995 at the Beals Island Regional Shellfish Hatchery (BIRSH; Perio Point, Beals, Maine) and overwintered according to Beal et al. (1994), were placed into plastic horticultural plant pots (15 cm diameter \times 15 cm deep) that had been filled with ambient sediments at an intertidal flat (Flake Point Bar, 44°36.75'N; 67°33.72'W) near Jonesport, Maine on 6 April 1996. Experimental units were distributed in three locations along a shore level gradient (low, mid and high intertidal) and stocked at one of three intraspecific densities (330, 660 and 1320 m⁻²). One-half of all units were covered with a piece of flexible, plastic netting (6.4 mm aperture) to deter predators (Beal et al. 2001). Ten replicates of each of the six treatments were used at each tidal height. To assess clam growth rate, units were collected on December 13, 1996, approximately one month after shell growth ceases in this region (Beal 1994) and two linear measurements (initial and final SL) were taken on all live clams using Vernier calipers to the nearest 0.1 mm. It was possible to discern the initial size of each hatchery-reared clam even though none was marked uniquely because each animal lays down a unique disturbance check in both of its valves at the time it is placed in the sediments (Beal et al. 1999).

In another study at Flake Point Bar, wild clams (size range = 21.4–79.5 mm) were collected from the upper ($n = 17$) and mid ($n = 23$) intertidal on November 11, 2004, and the animals aged using annual rings (Newcombe 1935) to estimate tide-specific age-length data. Ford-Walford plots were used to generate von Bertalanffy growth curves.

Addison

On May 10, 2001, hatchery-reared clams (12.4 ± 1.4 mm SL; stocking density = 535 individuals m^{-2}) were added to 24 plastic horticultural pots (as described earlier) that contained ambient sediments at 4 intertidal sites chosen by Addison's shellfish committee (Batson's Beach: $44^{\circ}31.65'N$; $67^{\circ}41.98'W$, Eastern Harbor: $44^{\circ}30.93'N$; $67^{\circ}43.37'W$, Three Brooks: $44^{\circ}33.56'N$; $67^{\circ}44.81'W$, Upper Pleasant River: $44^{\circ}35.82'N$; $67^{\circ}44.58'W$). At each site, experimental units were arrayed in six blocks of four units each (2×2 matrix per block with 1-m spacing between rows and columns). To deter predators, in each block, a thin, flexible piece of plastic mesh netting (aperture = 6.4 mm) was affixed to the top of two units using rubber bands, whereas the other two received no netting. Blocks were spaced about 2 m apart and placed between the mid to low intertidal at each site. All units were removed from three of the sites on November 16, 2001, whereas the units were removed from Three Brooks on November 21, 2001. Growth rates for each living clam was determined as described earlier.

ANOVA was conducted on the untransformed mean final SL using the following linear model:

$$Y_{ijkl} = \mu + A_i + B_j + AB_{ij} + C(A)_{k(i)} + BC(A)_{j(k)} + e_{l(jk)},$$

where

μ = theoretical mean;

A_i = site ($i = 4$ sites, factor is fixed);

B_j = Netting Treatment ($j = 2$, protected versus unprotected, factor is fixed);

C_k = Block ($k = 6$ blocks per site; factor is random); and,

e_l = experimental error.

RESULTS

Eastport

Most (93%) of the clams in the lower plots were recovered dead with a countersunk hole, typical of predation by the moon snail, *Euspira heros* Say. Only 1 of 68 marked clams was found alive in plots 1a-4a (lowest tidal heights). That animal grew 1.5 mm over the year from 49.6–51.1 mm. Similarly, in a plot with unmarked animals (3b), one live clam (of 27 planted) was found, and it had grown only 4 mm from 38.0–42.0 mm. Plot 4b contained only 3 live, unmarked clams (one had grown 1.9 mm from 54.1 mm to 56.0 mm, the second grew 0.5 mm from 49.1 mm to 50.6 mm, and the third grew 0.8 mm from 48.5 mm to 49.3 mm).

Clam survival in lower mid to upper intertidal plots at Carrying Place Cove (5–10) varied from 50% to 81%, which yielded sufficient data to estimate annual growth rates (Fig. 4). The time to reach a legal size of 50.8 mm SL varied directly with tidal height and sediment type. The growth curves of clams from plots near the lower mid tide (Plots 5 & 6) demonstrate that it would take between 4.5–5.5 y to reach 50.8 mm. Clams in clay sediments within

Figure 4. von Bertalanffy growth curves of wild clams along a tidal gradient at Carrying Place Cove, Eastport, Maine from April 22, 1998 to April 20, 1999. The dotted line parallel to the x-axis is the minimum legal size of softshell clams in Maine (50.8 mm, or 2-inches SL).

Plots 7a, b, near the upper mid tide, take 7–8 y to reach legal size; however, animals in adjacent plots at the same tidal height but in more sandy sediments (Plots 8a, b) reach this size in 6.5 y. Growth rate of clams at or near the highest tidal mark are extremely slow (Fig. 4), and animals there may never attain legal size (pers. obs.).

Jonesport

No effect caused by predator exclusion ($P = 0.0696$) or stocking density ($P = 0.0890$) on clam growth was detected from April to December 1996; however, tidal height effects were highly significant ($P < 0.0001$). Final mean SL of animals at the lowest intertidal was 35% greater than those at the mid tide level and 95% greater than those at the upper intertidal. In addition, growth variation decreased significantly from the lowest to highest tidemark (Fig. 5).

From the November 2004 sampling, clam growth was faster at the mid intertidal versus the upper intertidal reflecting differences in tidal inundation (Fig. 6). Clams attain a size of 50.8 mm in 5.8 y at the mid-tide level and 7.8 y near the upper intertidal.

Addison

No differences in growth were observed between clams protected with netting and those that remained unprotected at any of the four sites for the 198-day experiment. Growth rate was fastest at Eastern Harbor where clams increased in SL by an average of 27.0 mm (final mean SL = 39.4 ± 1.2 mm) and slowest at Upper Pleasant River where final mean SL was 31.2 ± 3.5 mm. A small percentage of clams (1.9% and 1.0%) attained at least 50.8 mm SL at Eastern Harbor and Three Brooks, respectively (Fig. 7). ANOVA indicated that site was the only significant source of variation (Table 3) and an *a posteriori* Student-Newman-Keuls (SNK) test demonstrated that clams at Eastern Harbor and Three Brooks attained significantly greater final mean SL's than clams at the other two sites ($P = 0.0001$).

Experiment III a and b

Dispersion and Growth of Hatchery-reared Juveniles of the Softshell Clam

Many of the small-scale field experiments conducted since 1989 (Beal 1994, Beal et al. 2001; Beal & Kraus 2002) have used

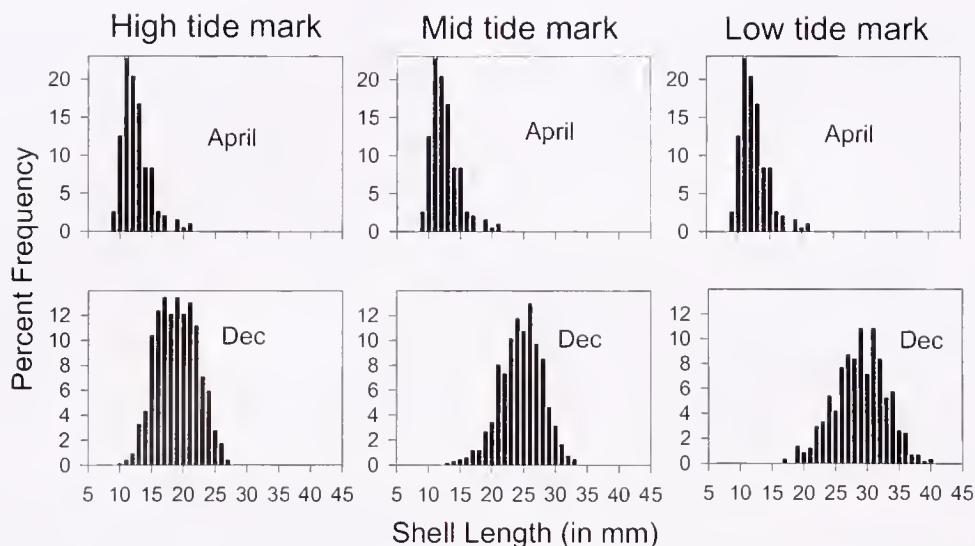

Figure 5. Size-frequency distributions of hatchery-reared clams planted at three different tidal heights at an intertidal flat near Jonesport, Maine from April 6 to December 13 1996. Mean initial SL = 12.4 mm. Most shell growth occurred between early June and August 6, but rates depended on tidal height (high, mid, and low tide plots = 55%, 42.2% and 45.2%, respectively). $n_{\text{April}} = 19$ for all tidal heights; n_{December} for high tide, mid tide and low tide clams = 758, 670 and 571, respectively.

plastic, horticultural plant pots (15.2 cm diameter \times 15.2 cm deep with a cross sectional area of 0.0182 m²). These experimental units are filled with ambient, unsieved sediments, and then buried to their rims in the sediments of a particular intertidal mud flat. Clam juveniles are then pushed gently to a depth of 12–15 mm under the sediment surface within the experimental units. These units are relatively easy to manipulate and establish various treatments within (e.g., stocking density, initial clam size, etc.). To discourage clams from emigrating from these units, a strip of flexible, plastic netting (4.2 mm aperture and measuring 10 cm \times 50 cm) typically is affixed to the outside circumference of each pot creating an open enclosure (*sensu* Beal et al. 2001). The netting, which extends 4–5

cm above the lip margin, purportedly acts as a fence to further decrease the probability of animals somehow escaping by themselves. Strips of the netting do not cover the top of the experimental unit and, therefore, allow predator access to the clams within the experimental units. Often, results of short-term field experiments reveal that missing rates from these open enclosures can be as high as 30% to 40% (Beal et al. 2001). Because the strip of netting is supposed to act as a barrier to emigration, it has been assumed that the missing clams are dead, the result of one or more predation events that directly or indirectly (tidal currents, wind, etc.) remove animals or their shells from the experimental units. In addition, it has been assumed that the strips of netting do not modify local currents and result either in a reduction or enhancement of shell growth.

METHODS

Experiment III a

To test the assumption that the flexible netting strips affixed to the experimental horticultural pot enclosures provide a barrier to migration, a laboratory and field test was designed. In the laboratory at BIRSH, 10 experimental units containing muddy sediments obtained from a nearby mudflat were established (as described earlier). On April 5, 1989, twelve hatchery-reared clams (4–6 mm SL) were added to each enclosure, and then the experimental units were placed in an array on the bottom of a 2,600-L fiberglass tank filled with ambient, unfiltered seawater (4°C). After one hour, during which time all clams had burrowed completely into the sediments, seawater was permitted to flow into the tank at a rate of ca. 5 l min⁻¹. After seven days at this flow rate, sediments in each experimental unit were washed through a 0.5-mm sieve, and all living and dead clams enumerated.

Emigration may depend on flow rate, varying submergence times, changes in temperature between immersion and emersion and other variables that are not controlled in a field setting. It is possible that experimental units with strips of mesh netting surrounding the periphery will act like a predator inclusion cage,

Figure 6. Age-length curves for wild clams collected on November 11, 2004 from two tidal heights at an intertidal flat near Jonesport, Maine. The dashed curve (diamond symbols) represents growth of clams near the mid intertidal ($n = 17$) whereas the solid curve (open circles) represents growth of clams near the upper intertidal ($n = 22$). The dashed line parallel to the x-axis is 50.8 mm, or minimum legal size (2-inches SL).

Figure 7. Size-frequency distribution of hatchery-reared softshell clams planted between the mid and low tide mark at four intertidal flats near Addison, Maine (May 10 to November 21 2001). Fastest growth occurred at Eastern Harbor and Three Brooks, where final mean SL \pm 95% CI = 38.9 ± 0.98 mm ($n = 38$) was significantly different ($P < 0.05$) from the final mean SL at the other two sites (32.8 ± 1.41 mm; $n = 31$).

enhancing predation by crabs and other consumers. Conversely, the flexible netting strip may deter predators and keep predation rates artificially low. Because laboratory studies cannot adequately reflect field conditions, the potentially confounding effects of emigration from experimental units also were evaluated in the field near the mid intertidal at a mudflat in the town of Cutler, Maine ($44^{\circ}41.22'N$; $67^{\circ}18.59'W$). On May 22, 2003, cultured clams (mean SL = 11.7 ± 0.25 mm) were added to experimental units (plastic horticultural pots) with and without a strip of flexible netting (as described earlier) at two stocking densities (12 or 24 clams representing 660 and 1320 m^{-2} , respectively). One half of all units were surrounded by an open ring of solid plastic (11.5 cm wide \times 29.0 cm diameter) that was pushed into the sediments 65 mm so that the experimental unit was in the middle of the open ring. The ring was used to help further contain clams that might emigrate from experimental units. The experiment was established as a completely randomized design with 10 replicates for each of eight fully factorial treatments (stocking density, $a = 2$ levels; netting strip, $b = 2$ levels; plastic ring, $c = 2$ levels). Enclosures were added to a 10×8 matrix, with 1-m spacing between rows and columns. Both short- and longer-term treatment effects were stud-

ied by randomly removing five replicates from each treatment from the matrix after 8 days, on May 30, 2003 and the remaining five replicates after 100 days, on August 30, 2003. Sediments from each experimental unit were washed through a 2-mm mesh. In addition, for units surrounded by a plastic ring, sediments within the area of the ring minus the area occupied by the experimental unit (i.e., 0.066 $m^2 - 0.018$ $m^2 = 0.048$ m^2) were sampled to a depth of 14 cm. Each of these samples was processed as described earlier. The relative growth of clams in units with and without strips of flexible plastic netting was assessed in the longer-term study. Relative growth = $([Final\ SL - Initial\ SL]/Initial\ SL) \times 100\%$. A relative growth value of 100% indicates a doubling in SL.

Experiment III b

Another assumption is that the strips of netting used to enclose juvenile clams within experimental units ($A = 0.0182$ m^2) do not affect their growth. On May 22, 2003, a generalized completely randomized block design (sensu Underwood 1997) was established at the mid intertidal of the mudflat in Cutler, Maine (see earlier). Eighty experimental units were filled with ambient sediments and pushed into the mud in blocks of four units each. Ten blocks contained units with strips of netting surrounding its periphery and extending above the sediment surface 4–5 cm (as described earlier). The remaining 10 blocks contained units without any strips of netting. Twelve hatchery-reared individuals (660 m^{-2}) were added to two of the units within each block, whereas the other two received 24 clams (1320 m^{-2}). Mean initial SL was 12.9 ± 0.4 mm ($n = 100$). On 29 August 2003, the contents of each experimental unit were sieved using a 2-mm mesh and the initial and final SL of each live clam measured to the nearest 0.1 mm using Vernier calipers. ANOVA was conducted on the untransformed mean relative growth using a linear model similar to that described (see **Experiment II: Addison**) earlier except:

A_i = Rim netting ($i = 2$, with and without; factor is fixed);

B_j = Intraspecific clam density ($j = 2$, 660 versus 1320 m^{-2} ; factor is fixed); and,

C_k = Block ($k = 10$ blocks per rimming treatment; factor is random).

TABLE 3.

Analysis of variance on the untransformed mean final SL of hatchery-reared individuals of *M. arcuaria* from 10 May to 21 November 2001 at four lower mid-intertidal sites in Addison, Maine. Ten clams (12.4 ± 1.4 mm SL) were added to protected (netting = flexible, 6.4 mm aperture) and unprotected experimental units ($A = 0.0182$ m^2) filled with ambient sediments and arrayed in six blocks per location. ($n = 2$ or 1 depending on survival.)

RESULTS

Experiment III a

All 120 clams were recovered alive from the experimental units within the tank at BIRSH, and none had escaped the enclosures.

In the short-term field trial, a small proportion of juvenile clams were missing (mean missing rate = $4.5 \pm 1.9\%$; $n = 40$). Missing rate was unaffected by stocking density ($F = 1.17$; $df = 1, 32$; $P = 0.4187$) or the presence of the strip of flexible plastic netting affixed to the outside circumference of each enclosure ($F = 0.13$; $df = 1, 32$; $P = 0.5625$). Of those experimental units rimmed with netting and further surrounded by a plastic ring, only one live clam of the 180 transplanted to those units (24×5 reps + 12×5 reps), or $<1\%$, had migrated from the unit (i.e., was found within the sediments outside the unit but within the area delineated by the plastic ring). For units without plastic strips of netting five clams were found in areas delineated by the ring. Two were alive (1.1%) and 3 were dead (2 with undamaged valves and 1 with crushed valves).

In the 100-day field experiment, the rate of missing clams pooled across all treatments was $24.7 \pm 3.2\%$ ($n = 40$); however, as in the case for the short-term trial, missing rate was unaffected by the presence of the strip of flexible netting ($\bar{x}_{\text{no netting}} = 27.1 \pm 5.1\%$ versus $\bar{x}_{\text{netting}} = 22.3 \pm 3.8\%$; $n = 20$; $F = 0.23$; $df = 1, 32$; $P = 0.6338$). The addition of a ring of plastic around experimental units helped determine the fate of missing clams. Only one live clam was sampled outside an experimental unit and within the area surrounded by the plastic ring (from an experimental unit without a strip of netting and stocked initially with 24 clams), whereas 40 clams were found dead, with crushed or chipped valves (typical of crustacean predation) in the same area. By adding the ring of plastic surrounding experimental units, the rate of missing clams dropped from $36.0 \pm 3.4\%$ (units without rings, $n = 20$) to $13.3 \pm 3.9\%$ (units with rings, $n = 20$) ($F = 29.09$; $df = 1, 32$; $P < 0.0001$). Stocking density did not influence rate of missing clams ($F = 3.92$; $df = 1, 32$; $P = 0.0565$).

Clams grew similarly in units with and without strips of netting ($P = 0.9948$). Mean relative growth in experimental units with strips of netting was $99.1 \pm 1.9\%$ ($n = 40$) whereas growth in units not surrounded by the rim of netting was $99.7 \pm 2.7\%$ ($n = 38$). In addition, no density effects on growth were detected ($P = 0.8174$).

Experiment III b

No significant difference in relative clam growth was found between experimental units with ($99.1 \pm 3.83\%$, $n = 40$) versus without the rim of netting ($99.7 \pm 5.56\%$, $n = 38$) used to enclose clams ($P = 0.9948$; Table 4). Mean final SL of clams in units with netting strips was 25.3 ± 0.51 mm versus 25.4 ± 0.57 mm for clams in units without the strips. In addition, stocking density had no effect on relative clam growth.

Experiments IV–VI

Predation Studies

Predation is the single most important and significant factor affecting survival of juvenile clams in eastern Maine (Commuto 1982b, Beal 1994, Beal et al., 2001, Beal and Kraus 2002, Beal in press). Efforts to deter predators using plastic netting have been used recently; however, when the exotic European green crab,

TABLE 4.

Analysis of variance on the untransformed mean relative growth of hatchery-reared juveniles (mean initial SL = 12.9 ± 0.4 mm) of the softshell clam, *Mya arenaria*, from 22 May to August 29, 2003 at an intertidal mudflat in Cutler, Maine. Experiment was designed to assess the interactive effects of stocking density (660 versus 1,320 m^{-2}) and the presence or absence of strips of mesh netting (4.2 mm aperture) surrounding the periphery of experimental units on clam growth.

Source of Variation	df	SS	MS	F	Pr > F

($n = 2$ or 1 depending on clam survival).

Carcinus maenas (L.), became a nuisance and major threat to clam populations in Maine during the 1950s. chicken wire (spread out over the flats and established as 0.5–0.75 m tall fences with a flange on top) was used to slow down and reduce the effectiveness of this crustacean predator within the intertidal zone (D. Wallace, Brunswick, ME, pers. comm.). Green crabs have been implicated as the cause of the sudden decline of the Maine softshell clam fishery during the 1950s (Glude 1955, Grosholz & Ruiz 1996; Fig. 1). Another major predator of *M. arenaria* in eastern Maine is the moon snail, *Euspira heros*. According to Commuto (1982b), this naticid gastropod preys on *Mya* until clams reach 30 mm SL, then mortality caused by *E. heros* is much reduced.

Here, results are presented from three field studies in eastern Maine to assess the importance of moon snail and green crab predation on wild and cultured individuals of the softshell clam.

METHODS

Euspira studies—Experiment IV August 1986 to June 1987

Because Commuto's (1982b) analysis of moon snail predation on softshell clams was indirect (age-specific survivorship estimates and size distributions of living and dead animals from samples taken near the high tide mark of a flat in eastern Maine on three dates), a field experiment was designed to test directly whether clams >30 mm SL attain a size refuge from *E. heros* attack. The intertidal study site, Hinckley Point ($44^{\circ}54.68'N$; $67^{\circ}12.21'W$), is at the confluence of the Dennys and Hardscrabble River near Dennysville, Maine. This site is approximately 12 km (Euclidean distance) from the site in Lubec (Federal Harbor; $44^{\circ}51.34'N$; $67^{\circ}04.72'W$) where Commuto (1982b) conducted his sampling. Wild softshell clams (15–51 mm SL) were dug from the immediate vicinity of Hinckley Point and 94 or 188 uniquely marked individuals were added to 0.25 m^2 plots ($n = 4$ replicates per density treatment) on August 4, 1986. Plots were marked with a wooden stake in each corner. Clams were grouped into four discrete size classes, which represented the natural distribution of clams at Hinckley Point (15–20 mm = 21%; 21–30 mm = 47%; 31–40 mm = 16%; 41–51 mm = 16%), and pushed into the sediments far enough to cover the posterior margin of each individual. Plots were revisited on June 11, 1987, when all live and

dead clams were removed and measured (SL) to the nearest 0.1 mm with Vernier calipers. Clams that had been attacked by moon snails had an obvious countersunk hole (or sometimes two) usually near the umbo of one of the valves. The mean borehole diameter from each dead clam was measured using a dissecting microscope with an ocular micrometer by measuring the greatest diameter of the hole and then taking a second measurement perpendicular to the first.

Because of the large number of dead clams with drilled valves, a laboratory trial was designed to determine the relationship between moon snail size and the diameter of the borehole it drills in the valves of its softshell clam prey to estimate size of predator in the field experiment. The study was conducted at BIRSH in late summer 1987. Twenty-one *Euspira* (SH = spire to apex; size range = 9–24 mm) were collected from Weir Cove (44°48.70'N; 67°08.26'W), an intertidal flat in Whiting Bay, approximately 12 km from Hinckley Point. One moon snail and five clams (size range = 16–52 mm SL) were added to each of 21 plastic boxes (10 cm × 10 cm × 6 cm deep) containing poorly sorted beach sand to a depth of 5.5 cm. Each box was covered with nylon window screening and individual containers were placed in running seawater (temperature = 14–15°C) for a two-week period. At the end of the trial, all *Euspira*, *Mya*, and boreholes were measured. To increase the scope of this relationship, a second laboratory experiment was conducted beginning on September 10, 1987. Four large moon snails (size range = 57–70 mm) were collected from the lower intertidal at Mill Cove (44°52.58'N; 67°09.71'W), also in Whiting Bay, and 5.2 km from Hinckley Point. One moon snail and ten clams (size range = 27–77 mm SL) were added to each of four 60-L aquaria containing 15 cm of poorly sorted beach sand and placed into running seawater (temperature = 15–17°C). Measurements of predator, prey, and mean borehole diameter were made as described above.

On October 22, 1987, 20 benthic cores ($A = 0.02 \text{ m}^2$) were taken near the upper intertidal at Federal Harbor in the vicinity where Commiato (1982b) had sampled from 1977–1979. Core samples were sieved through a 0.5-mm mesh. The SL of each *Mya* with a bored valve and its borehole diameter was measured (as described above), and then the *Euspira*-borehole relationship was used to estimate the size frequency distribution of moon snail predators at Federal Harbor.

Euspira studies—Experiment V. June to September 1993

To assess how moon snails respond to increasing juvenile clam density along a tidal gradient, a field test at a mudflat near Bell Farm Cove in Edmunds, Maine (Whiting Bay: 44°49.33'N; 67°09.24'W) was initiated on June 22, 1993. Plastic plant pots (as described earlier) were used as experimental units that were arrayed in a single 5 × 6 block at each of 3 tidal heights (high, mid and low). Within each block, hatchery-reared juvenile softshell clams (mean SL = 8.9 ± 0.62 mm; range = 4.2–15.3 mm) were added to the open enclosures at one of two stocking densities (12 or 24 clams per unit, or 660 or 1320 m^{-2} , respectively). Five replicates of each of the six treatments ($a = 3$ tidal heights × $b = 2$ densities) were removed from the flat on July 22, August 22 and September 20, 1993. The contents of each experimental unit were sieved through a 2-mm mesh. The initial and final SL of all clams with countersunk boreholes, typical of *E. heros* attack, was measured to the nearest 0.1 mm using Vernier calipers. Mean borehole diameter of each drilled valve was measured using a dissecting

microscope with ocular micrometer. An arcsine transformation was applied to the mean percent dead drilled, and then a model 1 3-factor ANOVA was performed to test for treatment effects. In addition, the *Euspira*-borehole relationship (as described earlier) was used to estimate size of moon snail preying on clams and whether predator size varied as a function of tidal height, stocking density and sampling date.

Carcinus studies—Experiment VI. October 1993

C. maenas has been presumed to be the major crustacean predator in most field experiments conducted in eastern Maine (Beal 1994, Beal et al. 2001, Beal & Kraus 2002). It is not difficult to identify general mortality agent based on shell damage in soft-shell clams. Typically, highest predation rates can be attributed to crab attack that is inferred from crushed and/or chipped valves. Field investigations have shown that crab predation is highly seasonal and varies along a tidal gradient (Beal et al. 2001). Predation rates caused by large crustaceans are relatively low at all tidal heights prior to August. From August until the beginning of October, rates are the highest observed during the year. Mortality of clams (ca. 12.4 mm SL) caused by crustacean predators was <20% for animals held in open enclosures near the high- and mid-water mark at an intertidal flat near Jonesport, Maine from April 6 to December 13, 1996 (Beal et al., 2001). However, mortality rates varied from 40% to 50% for animals in open enclosures near the low tide mark over the same period. Protective netting enhanced clam survival only at the lowest tidal elevation where difference in mean survival between units with and without the predator deterrent mesh was nearly 30% ($\bar{x}_{\text{protected}} = 91.1 \pm 4.5\%$ versus $\bar{x}_{\text{unprotected}} = 63.3 \pm 9.7\%$, $n = 120$, $P < 0.0001$).

Beal and Kraus (2002) examined the interactive effects of protective netting, initial clam size and stocking density on clam survival in separate studies at two intertidal locations near Jonesboro and Cutler, Maine. From June 1990 to June 1991, crushing predators accounted for 33.6% and 20.3% of losses of clams initially 8.5 and 11.8 mm SL, respectively, in open enclosures. From April to October 1991, losses of clams initially 14.6 mm from open enclosures ranged from 15% to 20%. Until now, however, identification of which crustacean species attacks juvenile clams in the intertidal has been indirect, based solely on shell damage.

To identify which crushing predators are active on clam flats during periods of tidal inundation, a passive trapping study was conducted at an intertidal flat in Cutler, Maine (see earlier) during October 1993. Vinyl-coated, wire lobster traps (61 cm × 55 cm × 38 cm), baited with salted herring (*Clupea harengus* L.), were placed outside and inside each of five sea grass beds (area of each bed ranged from 150–250 m^2). Distance between traps from outside to inside a bed was no more than 15 m. The test was initiated at low tide on October 1 and traps were checked irregularly (on 10 dates) at periods of low water until October 21. New bait was added to each trap on each sampling date, except the last. When a crab was found within a trap, it was measured (greatest carapace width to the nearest 0.1 mm) and its sex recorded. Before releasing trapped crabs, the dactyl from each pair of fourth walking legs was excised. This provided a common mark that I used to distinguish animals caught more than once.

RESULTS

Euspira—Experiment IV

Of 1128 clams transplanted initially to the eight field plots in August 1986, only 600 were recovered (47% were missing), and of

these, 215 were alive and 385 were dead. Growth rates were extremely slow with animals >40 mm exhibiting no significant shell growth and animals <40 mm exhibiting increases in SL between 3 and 5 mm. Approximately 77% (296) of the total number recovered dead had been drilled by *Euspira* (Table 5). Moon snails did not demonstrate a density-dependent response to their prey based on total number per plot or initial size ($G = 2.8$, $df = 3$, $P = 0.43$) but did show a preference for clams between 31 and 40 mm SL. A comparison of the initial size distribution versus the size distribution of drilled individuals (Fig. 8) reveals that *Euspira* fed selectively on different size clams ($G = 84.9$, $df = 3$, $P < 0.0001$). Examination of the expected frequencies within the 2×4 contingency table revealed that the proportion (6%) of drilled clams in the smallest size category (15–20 mm) is three times lower than expected (18%) and the proportion (38%) of drilled clams between 31–40 mm is nearly double the expected frequency (20%).

The relationship between mean borehole diameter and snail size (Fig. 9), allows one to estimate the size of snails drilling clams in the field (Fig. 10). Moon snails at Hinckley Point flat ranged in size from approximately 10–52 mm in shell height. Nearly 70% of the moon snails preying on *Mya* were between 20–30 mm. Mean snail size ± 1 SE was 24.4 ± 0.30 mm ($n = 296$). Conversely, moon snails at Federal Harbor were smaller ($\bar{x} = 11.9 \pm 0.29$ mm), and ranged from 8–29 mm ($n = 94$). The two distributions were significantly different ($P < 0.0001$; G-test of independence).

Euspira—Experiment V

From June to July 1993, $71.5 \pm 8.13\%$ ($n = 30$) of the *M. arenaria* juveniles were recovered dead with drilled valves, and this rate increased through time ($P = 0.0066$). There was no difference in mean percent with drilled valves from the final two sampling dates ($81.7 \pm 4.06\%$, $n = 60$; $P = 0.1403$). Mean snail size varied significantly with date, tidal height and stocking density (Table 6). Snails were smaller in June (16.5 ± 1.06 mm, $n = 29$) than they were in July and August (17.6 ± 0.89 mm, $n = 60$), decreased in size from the high (20.6 ± 0.94 mm, $n = 30$) to the mid and low tide mark (15.5 ± 0.52 mm, $n = 59$) and increased in size with increasing intraspecific clam density (mean SH of snails

Figure 8. Initial size-frequency distribution of clams used in a field experiment from August 4, 1986 to June 11, 1987 and the distribution of clams with a bored valve from moon snail, *Euspira heros*, attack. Size classes of clams (SL) are: I = 15–20 mm; II = 21–30 mm; III = 31–40 mm; IV = 41–51 mm. The two distributions are different ($P < 0.0001$) indicating that snails prefer a particular size *Mya*. Clams in size class III were drilled at a rate that was nearly double than what was expected ($P < 0.05$; G-test of independence). Conversely, clams in size class I were drilled less frequently than expected.

in units stocked at 660 vs. 1,320 m^{-2} was 16.5 ± 0.90 mm vs. 17.9 ± 1.02 mm).

Carcinus—Experiment VI

Thirty-one green crabs (mean carapace width, CW = 72.6 mm) and 22 rock crabs, *Cancer irroratus* Say (mean CW = 97.6 mm), were caught in the traps during the test interval. All crabs were male, and no individual was caught more than once. Fewer crabs were caught near the end of the month than at the beginning, and each species demonstrated a preference for one location over another ($P = 0.02$). Green crabs were 4.1× more likely to be caught inside eelgrass beds than outside them, whereas

TABLE 5.

Fate of *Mya arenaria* at two densities ($1 \times = 94 m^{-2}$, $2 \times = 188 m^{-2}$) from 4 August 1986 to June 11, 1987 at Hinckley Point Flat, Dennyville, Maine. n = number of clams at the beginning of the experiment, A = percent recovered Alive, UV = percent recovered dead with Undamaged Valves, DV = percent recovered dead with countersunk, Drilled Valves, CV = percent recovered dead with Chipped or Crushed Valves. One-way ANOVA on the angular-transformed mean percent with drilled valves (DV) failed to detect significant differences due to stocking density.

M = percent Missing.

Figure 9. Relationship between mean borehole diameter (in the valves of *M. arenaria*) and size of moon snail predator. Dotted lines represent 95% confidence intervals. $Y = 0.058 + 0.0512 X$, $n = 138$, $r^2 = 0.884$, $P < 0.0001$.

Figure 10. Estimated size-frequency distribution of moon snails from Federal Harbor, Lubec, Maine ($n = 94$), where Combito (1982h) concluded that soft-shell clams reach a refuge from moon snail attack after they attain a SL of 30 mm, and from Hinkley Point, Dennysville, Maine ($n = 296$). Both distributions were created by measuring the mean borehole diameter of clams collected from both sites and then using the linear equation relating borehole diameter to snail size (see legend of Fig. 9).

rock crabs were 2.7 \times more likely to be found in traps on the unvegetated muddy sediments. The results indicate that assigning all crushing and chipping damage to green crabs is not appropriate and that it is possible that rock crabs prey on small softshell clams in the intertidal zone during periods of tidal inundation.

DISCUSSION

In Maine, USA, intertidal populations of softshell clams are a public resource that is managed by the local community in co-

TABLE 6.

Analysis of variance on the untransformed mean size (shell height) of moon snails (*Euspira heros*) attacking hatchery-reared juveniles of *Mya arenaria* from June 22 to September 20, 1993 at an intertidal flat near Bell Farm Cove, Edmunds, Maine. Clams were stocked at one of two densities (660 or 1,320 m^{-2}) at three tidal heights (high, mid, low) and samples on three dates: July 22, August 22, and September 23. A decision rule of $\alpha' = 0.0253$ was used for each single degree-of-freedom, orthogonal contrast involving sampling date and tidal height.

Source of variation	df	SS	MS	F	Pr > F
Sampling date	2	30.03	15.01	3.70	0.0297
(1) June versus July & August	1	29.73	29.73	7.32	0.0086
(2) July versus August	1	0.30	0.30	0.08	0.7846
Tidal height	2	525.69	262.85	64.68	<0.0001
(1) High versus mid & low	1	524.27	524.27	129.01	<0.0001

($n = 5$).

operation with State government and its regional shellfisheries biologists. Two decades ago, approximately one-half of coastal communities along the Maine coast actively managed their soft-shell clam fishery through local ordinances. Today, that percentage is 70%, and, although most of these communities participate in some form of active management efforts to enhance stocks (e.g., clam transfers, netting to encourage spatfall, planting hatchery-reared seed), all benefit from restricted, or limited entry, which results in an approximate 15% higher yield for harvesters than those in communities without local management plans (Townsend 1985).

Clam Transfers

Today, approximately 44% of Maine communities that manage their *M. arenaria* stocks participate in some form of clam transfer program (ME DMR 2005) by harvesting clams from areas of high density and replanting them in areas with lower clam abundance (usually lower on the shore). To date, however, only anecdotal information exists about the efficacy of these activities. Generally, seed clams (animals <50.8 mm SL that typically range from 38–45 mm SL) are dug by hand by groups of clambers, and then immediately (or within 24 h) replanted by broadcasting the animals from a boat at high tide into a closed intertidal area. Clams may take up to 72 h to reburrow because burrowing rate depends on clam size and seawater temperature (Zwarts & Wanink 1989, Zaklan & Ydenberg 1997). At present, no shellfish committees apply netting to the reseeded area to deter predators. Further, no community chooses to follow the fate of the transferred animals. Instead, success is measured by the number or volume of clams transferred during any given effort. Although a single field test on clam transfers was conducted and generalizations should not be made, results presented here suggest that if communities choose to participate in clam transfer programs, they can improve production in the reseeded areas simply by using protective netting. This would have to be done at low tide when it would be possible to secure the netting around the seeded plot, however. Netting did not meet the criteria of statistical significance in this study, but did result in an overall 120% increase in final mean density compared with the density of transferred clams in plots without netting. It is unclear, however, whether the netting acted only to retain clams in the seeded areas or improve seed survival by deterring predators. Another benefit of using the plastic, flexible netting was that it enhanced wild recruitment 3-fold compared with control plots.

The transfer field experiment was conducted to provide several biological parameters to help the city of Eastport's shellfish conservation committee decide what steps it should take regarding this management option. No cost-benefit analysis was done; however, in eastern Maine, where large numbers of adult clams occur in the extreme upper intertidal zone, and where growth rates are very slow and legal sizes may be attained only after 10 years (Fig. 4), these efforts may be cost-effective and necessary. Results from this study suggest that growth rate of clams from these high intertidal areas is plastic as they assume rates of shell accretion that is typical of the area to which they are transferred (see also Dow & Wallace 1961). Transfer efforts may allow some communities to harvest clams legally that they may not be able to do otherwise. Typically, clams in these high intertidal areas are not harvested and left to grow and presumably reproduce. It is unknown, however, whether these "refuge populations" act as natural spawner sanctuaries (sensu McCay 1988), and if clam transfer efforts were to increase

whether this would have any effect on natural recruitment in that region.

Shell growth

Growth of infaunal and epifaunal bivalves in the intertidal zone typically is related to submergence time, varying inversely with tidal height (Mead & Barnes 1904, Newcombe 1935, Jordan & Valiela 1982, Vincent et al. 1989, Stiven & Gardner 1992). Several investigations, however, have shown that although bivalve growth may be faster lower on the shore than in the upper shore area, rates do not necessarily parallel directly submergence times (Peterson & Black 1987, 1988, Beal et al. 2001). The yearlong study at Carrying Place Cove in Eastport (April 1998–1999) demonstrated that clams at the mid and upper intertidal zones grew faster than animals at the extreme low intertidal. Only 5 of 216 clams planted in open plots near the low intertidal survived (2.3%), and these grew extremely slow (e.g., 1.9 ± 1.5 mm SL). Survival was significantly higher in plots near the mid and upper intertidal, where growth rates followed expected patterns (Fig. 4). Why was growth so slow among clams in the lower intertidal zone where they were submerged nearly 100% of the time? Intraspecific competition can be ruled out because survival rates were so low. Interspecific competition may explain partially this result, because the plots were adjacent to subtidal beds of blue mussels, *Mytilus edulis* L. Another factor may have been disturbance caused by the predatory activities of the moon snail, *Euspira heros*. After measuring the borehole diameters of the drilled clams and using the *Euspira*-borehole diameter equation (Fig. 9), it was determined that the mean snail size preying on the clams at the mean low tide level was 40.0 mm. Reductions in shell growth have been attributed to predators in several field studies. For example, the shell growth of hard clams, *Mercenaria mercenaria* (L.) was nearly 100% slower when animals were exposed to whelk attack (Nakaoka 2000). Similarly, Peterson and Black (1993) observed a 50% reduction in growth of *Katelysia scalarina* Lamarck and *K. rhytiphora* Lamarck in full cages versus open enclosures in Western Australia that was presumably because of increased disturbance by a predatory seastar that had gained entrance to the protected cages.

The growth of juvenile softshell clams in protected and unprotected experimental units was followed in experiments conducted in Jonesport and Addison, Maine. Neither test demonstrated a significant difference in final mean SL between the two treatments, a result consistent with Beal and Kraus (2002). Results from the Addison study indicate the importance of spatial variability in clam growth rates as juveniles at two of the sites exhibited significantly faster growth (20% difference in mean SL) than those at the other two sites. Differences in final SL were not associated with variation in tidal height as experimental units at all four sites were deployed at a single tide level. Spatial differences in bivalve growth may be related to differential microalgal concentrations in the water column that have been found to differ dramatically between adjacent sites (Posey et al. 2002, Carmichael et al. 2004), a reflection of spatial differences in biological disturbance, or differences in sediment composition (Newell & Hidu 1982).

A small percentage of clams in the Addison study attained legal size in one growing season (May to November). From May to November 2001, clams added an average 27.2 ± 1.17 mm ($n = 22$) and 25.5 ± 1.71 mm ($n = 22$) of new shell at Eastern Harbor and Three Brooks, respectively. These growth rates are faster than

reported for this species anywhere in Maine (Dow & Wallace 1953, Spear & Glude 1957, Newell & Hidu 1982, Commito 1982b, Beal 1994). In addition, these rates are faster than those reported for 0-y class individuals of *Mya* in northern Massachusetts (Brousseau 1979).

Previous field studies with hatchery-reared juveniles of *M. arenaria* (Beal 1994, Beal et al. 2001, Beal & Kraus 2002) assumed that the rim of netting used along the periphery of the small experimental units to enclose clams (but still allow predators access to the clams in the unit) did not affect clam growth. Although results presented here and elsewhere (Beal et al. 2001) have demonstrated that completely covering the top of experimental units with protective netting has no significant effect on clam growth, Experiment III a & b tested the assumption explicitly. Those results revealed that published growth rates are not confounded by the addition of a strip of netting projecting 4–5 cm above the surface of the sediments. Relative growth rate and final mean SL were nearly identical in both tests.

Predation

The three field experiments involving moon snails and green crabs add to an extensive literature on the importance of predation in controlling populations of juvenile and adult softshell clams in Maine (Commito 1982a, b, Thiel 1997, Ambrose et al. 1998, Beal et al. 2001, Beal & Vencile 2001, Beal & Kraus 2002, Whitlow et al. 2003). Although moon snails, *Euspira heros*, occur along the entire coast of Maine, their numbers (as estimated by their predatory activities associated with *Mya*) seem to be greater in eastern Maine than elsewhere (Beal, pers. obs.). Softshell clam seeding activities using cultured juveniles produced at BIRSH that have occurred in each coastal county of Maine (1987–2005) and mortality caused by moon snails is problematic only in eastern Maine (Washington County). By analyzing size-frequency data of both predator and prey populations at Federal Harbor in Lubec, Maine from 1977–1979, Commito (1982b) demonstrated that soft-shell clams escape moon snail predation by growing relatively quickly (over 5 y) to a refuge size of 30-mm SL. Moon snails at the upper intertidal of Federal Harbor rarely exceeded 30 mm in shell height.

On numerous occasions in 1984 and 1985 while inspecting intertidal flats in Cobscok and Whiting Bays, many dead, drilled *Mya* were discovered that were >50 mm SL. The experiment at Hinckley Point from 1986–1987 demonstrated that an absolute size refuge of 30 mm from moon snail attack may be common at some intertidal flats, but not at others (Fig. 10), because moon snail size may vary along a tidal gradient. *Euspira* occurs both in the intertidal and subtidal in Maine waters. Larger moon snails (up to 100 mm in shell height) are found below mean low water, whereas smaller animals are found from mean low water to the high water mark (B. Beal, pers. obs.). It is likely that a gradient of refuge sizes exist for *Mya* from *E. heros* attack that increases in SL from the upper to lower shore levels. Besides the Hinckley Point study that indicated more clams in the 31–40 mm size range fell victim to moon snails than was expected by random chance alone, high mortality rates occurred in clams >30 mm SL in Eastport (Experiment II) at the lowest tidal level from 1998–1999. Subsequent analysis of mean snail size using the *Euspira*-borehole diameter relationship (Fig. 9) showed that snails preying on clams at that site averaged 40 mm in shell height. Similar analysis of boreholes in drilled *Mya* from the Hinckley Point experiment showed that some moon snails were as large as 52 mm in shell height.

Moon snails are voracious predators of juvenile softshell clams. The study conducted at Bell Farm Cove in 1993 demonstrated that approximately 70% of juveniles <10 mm SL were preyed on by *E. heros* during the first month, from June to July. Although mean snail size was <20 mm at all tidal heights at that site, animals were significantly larger nearer the high versus mid and low tide levels. Maximum snail size was estimated to be 30 mm SH. Vencile (1997) determined that moon snails drill clams that are approximately similar in SL to their shell height. In this study, a similar relationship existed (Snail size = $10.37 + 0.689 \times \text{SL}$, $n = 1262$); however, clam SL explained only 6% of the variation in snail size.

Green crabs, *C. maenas*, are perhaps the best known, and most widely studied, predator of juvenile and adult soft-shell clams in Maine and the northeast United States (Glude 1955, Ropes 1968, Hunt & Mullineaux 2002, Whitlow et al. 2003, Hunt 2004). Intertidal field studies in eastern Maine have demonstrated the efficacy of excluding large crustaceans from experimental units containing softshell clam juveniles (Beal 1994, Beal et al. 2001, Beal & Kraus 2002). For example, between April and September, clam survival in the low intertidal zone at Flake Point Bar, Jonesport, Maine varied from 83% to 103% higher in protected versus open experimental units (Beal et al. 2001). Mean losses exceeded 50% in open enclosures, and, because *C. maenas* was found in some open enclosures, this predator was assigned as the mortality agent. The trapping study conducted in Cutler, Maine reveals that *Cancer irroratus* does forage intertidally during periods of tidal inundation.

It remains to be seen whether differences in *Mya* shell damage exist between these two large crustacean predators.

ACKNOWLEDGMENTS

The author thanks the staff at the Beals Island Regional Shellfish Hatchery who, over the years, has worked tirelessly to produce softshell clams for enhancement and research purposes. Each experiment required the assistance of many people both in the field and laboratory. The author thanks S. Allard, C. Bartlett, W. Hopkins, and students from the marine resources program at Shead High School in Eastport, Maine who helped with Experiment I. C. Bartlett (Eastport), M. Parker & K. Vencile (Jonesport), and W. Walton (Addison) helped in the field with Experiment II. In addition, students from grades 5–6 at Jonesport Elementary and Beals Elementary helped take samples in November 2004 at Jonesport. University of Maine at Machias students P. Pandey, M. Rudin, and J. Wagner assisted in the field and laboratory with Experiment III a & b. W. Spear assisted in the field during Experiment IV. The author thanks R. Bell and T. Bell for permitting access to the flat at Bell Farm Cove and D. Monroe for permitting access to Duck Brook Flat in Cutler. J. Buker, B. McCollum, and K. Vencile assisted with all aspects of Experiment V, and J. Rodzin helped bait traps and measure crabs for Experiment VI. The author also thanks the University of Maine at Machias, Cobscook Bay Resource Center, Maine Sea Grant College Program, and the Davis Conservation Foundation (Falmouth, Maine) for collectively supporting these efforts.

ABSTRACT The soft-shell clam, *Mya arenaria* (L. 1758), has the highest landed value of Maine bivalves. Landings have been variable over the last century with current landings one third of their historical highs caused by low harvests in Eastern Maine. Diminished clam populations have been subjected to constant fishing pressure and heavy predation by green crabs apparently unchecked by winterkill. Clam stocks previously closed to harvesting because of pollution are now dug. Reduced breeding populations are tasked to produce a sufficient set to overcome offshore dispersal of larvae to repopulate flats on the coast of Maine. On-bottom and off-bottom sampling found few clam larvae in Eastern Maine. Recovery of the fishery will require reestablishment of breeding stocks.

KEY WORDS: clam landings, Gulf of Maine, green crabs, shellfish management.

INTRODUCTION

The softshell clam *Mya arenaria* supports the major bivalve industry in the State of Maine with a landed value of \$16.61 million dollars in 2004. Since the early 1980s clam landings have declined by two-thirds. Washington County produced about two-thirds of the State landings in the 1970s but decreased to between 20% to 45% of landings in recent years (see Fig. 2 later).

Trends in landings seen in Figure 1 and Figure 2 comparing southern (S) versus eastern (E) Maine, do not show a regular cyclical trend in landings statewide, although Washington and Hancock counties have had two distinct peaks in landings over the past 50 years.

Management and Regulation

In 1901 Maine authorized towns to license diggers and regulate digging. Most soft-shells were canned. From 1901 to the 1930s, the State limited the canning season from September 15 to June 1. Shipping live clams out of state was prohibited. Summer digging was banned until 1937 when the three counties in the southwest lifted a ban because of the demand for live and shucked clams throughout the region (Fig. 1). In 1947 restrictions on summer digging and transporting clams were lifted in Lincoln County and restrictions in the rest of the State were removed in 1949. By 1958, only 10% of the catch was canned (Wallace 1997).

A minimum harvest size has been used as a clam conservation measure throughout the region. A two-inch minimum size law was passed by Maine in 1935 and repealed in 1963 (Fig. 1) when Maine authorized coastal municipalities to establish local ordinances to regulate digging and implement conservation measures. The number of towns with a local clamming ordinance increased to 45 in 1988 and 74 in 2003. In 1984, the 2-inch minimum harvest size was reestablished by Maine. Massachusetts has had a 2-inch softshell minimum for harvesting since the early 1900s (MacKenzie 1997). In the Bay of Fundy, New Brunswick and Nova Scotia both have a 44 mm (1.75-inch) minimum harvesting size (Jenkins et al. 1997).

Fishing pressure on clams is limited by the number of harvesting licenses issued. The number of licensed diggers increased from 500 in 1888 to 2,600 in the late 1940s after World War II (Fig. 1). The number of licenses remained relatively constant until an in-

crease in the number of licenses in the 1970s corresponded with an increase in catch. Although catch had decreased by 1991 to levels not seen since 1959, the number of licenses decreased but remained above the number of licenses issued before the 1970s (Wallace 1997). Between 1990 and 2001, Cumberland and Lincoln counties issued the most licenses in S Maine with average clam harvest per license of 1,284 and 800.0 lb/license, respectively. In E Maine, despite the decline in landings in the early 1990s, the number of licenses remained relatively constant resulting in a lower catch per unit effort of 469 and 525 lbs per license in the same period. The recent increase in landings in Washington and Hancock counties (Fig. 1 & 2) in the mid 1990s has been matched by an increase in the number of licenses issued in these counties from 1,268 in 1996 to 1,940 in 2001. Consequently, catch per unit effort in these counties has remained low (Fig. 3).

Effort dedicated to clam management varies between municipalities. In 2002 Maine Department of Marine Resources data for appropriations for management and clam resource value for towns, the correlation between expenditures for management and value of clam landings was 0.41 ($P < 0.01$, $n = 54$). Of towns that listed expenditures for clam management, E Maine towns averaged \$443 for management appropriations in 2002, whereas Southern and Midcoast Maine averaged \$1206.

Pollution Closures

In 1946, Maine closed polluted waters under the National Shellfish Sanitation Program (Fig. 1). In 1974, 3,420 residential direct discharges of sewage had been identified. This number had decreased to 2,446 in 1992, but the number of prohibited acres closed to clamming peaked at about this time. Between 1985 and 1993, the total acreage closed to clamming increased (Fig. 4), whereas landings went down correspondingly perhaps because of a restricted fishing area (Wallace 1997). Before 1990, the DMR estimated that approximately one-third of all productive clam flats in Maine were closed because of pollution (Farrey et al. 1997). Opening flats resulted in an immediate increase in landings. Acreage closed to harvesting, decreased from 270,444 in 1993 to 153,847 acres in 2002; most of the closed acreage was in the S Maine. In New Brunswick, Canada about half of the flats were closed because of pollution in the mid 1990s and these closures were considered relatively permanent (Jenkins et al. 1997).

Figure 1. Maine softshell clam landings by year with northern limit of green crab range and years of implementation of management practices. Rectangles plot number of clam licenses issued.

Gulf of Maine Tidal Dispersion

Tides and tidal currents in Gulf of Maine increase to the north and east. The tidal range is 3.4 m in Barnstable Harbor, on north side of Cape Cod, increasing to 6.5 m in Eastport in E Maine. Tidal flushing can be measured by determination of an exchange ratio and/or flushing time. The tidal exchange ratio is the ratio of bay volume at high tide to the total tidal flow. Flushing time is time required to replace the total volume of water. Flushing time decreases and exchange ratio increases with tidal amplitude.

Barnstable Harbor is at the southern end of the Gulf of Maine. In the 1940s and 1950s, the clam populations in the harbor decreased to negligible proportions and efforts to reestablish were largely unproductive (Ketchum 1954). Using a conservative exchange ratio for Barnstable Harbor of 0.3 (tidal volume 30% of bay volume), Ketchum (1954) estimated ~0.01% of the larvae spawned in the harbor would be retained to set. Offshore flushing was identified as the likely reason that "only rarely indeed is a substantial set obtained."

Tidal flushing would move clam larvae away from the mudflats where they are spawned. Edwards & Sharples (1986) estimated flushing times for 110 Scottish lochs using tidal range, low water residual volume and the water surface area at low and high water.

Figure 2. Eastern (Washington and Hancock) and southern and mid-coast Maine softshell clam landings by year.

Figure 3. Catch per license issued in counties in Southern Maine (Cumberland and Lincoln) and Eastern Maine (Washington and Hancock).

Flushing times varied from <0.5 to 14 days, with the shorter flushing times for small, shallow lochs and longer flushing times for deep-sea lochs. Using the same technique, flushing time of Quahog Bay on the mid Maine-coast (mean tidal range of 4.0 m and high water area of 4.3 km²) was estimated to be 1.25–1.5 days (Holte et al. 2003).

To determine the effect of a larger tidal range on flushing time, flushing times were determined for two bays in E Maine. Both bays had a tidal range of 5.2–5.3 m, but differed in size: high water area of Mason Bay is 3.7 km²; high water area of Englishman Bay is 131.7 km². Using the technique of Edwards and Sharples (1986) flushing times was determined as: 0.281 days for Mason bay and 1.8 days for Englishman bay.

A flushing time of <0.5 is less than one tidal cycle. Mason Bay, with an estimated flushing time of 0.281 days, drains nearly dry on spring tides. Low flushing times and high exchange ratios in Gulf of Maine bays, could be responsible for dispersing larvae offshore away from their native mudflats. Offshore dispersion of clam larvae would be expected to be greater where the tides are larger (i.e., E Maine relative to S Maine). Tidal processes would also be expected to have more effect on larval dispersal in the Gulf of Maine relative to bays and estuaries south of Cape Cod where tides are seldom greater than 1.5 m.

Figure 4. Maine pollution closure (acres) and landings (lbs/1000).

Data—Clam Sets Along the Maine Coast

Mudflats in different parts of Maine were surveyed for year 0 juveniles to compare clam sets in different parts of Maine. Core samples from mudflats were collected from E and S Maine in late fall and winter for 2 years and sieved. Juvenile clams (1.8–6.0 mm) from the set of the preceding summer were counted. Densities of juveniles averaged $16.9/\text{m}^2$ from 120 samples from E Maine and $204.5/\text{m}^2$ from 120 samples in S Maine (Vassiliev et al. 2000). *Mya* off-bottom settlement was also sampled with spat bags filled with monofilament line in locations in E and S Maine and retrieved monthly. Spat bags placed inside and outside the Scarborough River in S Maine had 484.4 ± 972.8 and 132.6 ± 189.5 juveniles/bag, respectively, compared with 2.2 ± 6.4 and 1.6 ± 6.3 juveniles/bag in the interior and outside of Mason Bay in E Maine. The differences between E and S Maine ($P < 0.001$) were statistically significant by *t*-test. The results of both of these samples suggest that the recent declines in clam harvests in E Maine may be at least partially caused by poor clam sets.

Predation—Green Crabs

Green crabs are a major predator of shellfish from newly settled juveniles to adults. Predation by juvenile green crabs and fish was found to be the ultimate factor controlling abundance of *Mya* juveniles in Barnstable Harbor, Massachusetts (Hunt & Mullineux 2002). Green crabs were scored as very serious shellfish predators (8.3 on a scale of 1–10 with 10 being the most damaging) in southern New England (Walton 2001).

Green crabs were not found north of Cape Cod (Fig. 1, Fig. 5) in 1872 (Smith 1879). By 1905, green crabs were found in Casco Bay in Eagle Harbor, Harpswell and the New Meadows River (Rathbun 1905). By 1930, samples had been collected as far east as Brooklin in Hancock County and by the 1930s, in Frenchmen's Bay and Winter Harbor in Hancock County, but they were not found in Washington County. By spring, 1951, their range extended eastward to Jonesport and Lubec. By the end of the summer

of 1951, they were found throughout Passamaquoddy Bay (Scattergood 1952).

Traps especially designed to catch green crabs were used by the Maine Bureau of Commercial Fisheries to sample crab populations from 1953–1960, and 1965–1967 (Welch 1968). In S Maine, crabs were trapped in Love's Cove, Southport. In 1953, daily trap catches at Love's Cove ranged from 110–670 crabs. Tagging and recapture studies estimated a population of 10,000 crabs per acre (Spear 1955b). Trap catches of green crabs declined in all areas sampled (Table 1) between the mid 1950s and mid 1960's (Welch 1968).

Figure 6 shows surface water temperatures recorded at Boothbay Harbor, Maine over the past 100 years. The years in which large numbers of green crabs were trapped on the Maine coast (Tab.1) were the years with extremely warm winter water temperatures (Fig. 6). Figure 1 and 2 show a decline in clam landings in the early 1950s when crab trap catches were high. In 1955, clam abundance in study areas was reported to have decreased by 50% over 4 years principally in places where green crabs were abundant (Glude 1955). As winter water temperature cooled in the 1960s, numbers of green crabs in E Maine declined sharply (Welch 1968). The fishery recovered in the mid 1960s (Fig. 1 & 2). In S Maine, green crab populations did not reach the low points observed in Eastern Maine and Canada (Welch 1968).

In recent years, sampling of green crabs in Maine has been limited. Green crab sampling was discontinued by the Maine Department of Marine resources (DMR) until 2001. In 1997 and 1998, green crabs were found in two locations sampled on Mt. Desert Island and two of three locations sampled in Casco Bay, but were not found in an estuary in Camden on Penobscot Bay (Whitlatch & Osman 1999). In the fall of 2002, 107 crabs per man-hour search were collected by DMR personnel at 12 sites along the Maine coast (Mercer 2003). This catch/man hour sampled is lower than the highest capture rate reported for Perry, Maine in 1953–1957 of 552/man hour, but higher than the low capture rate of 7/man hour in 1960–1965.

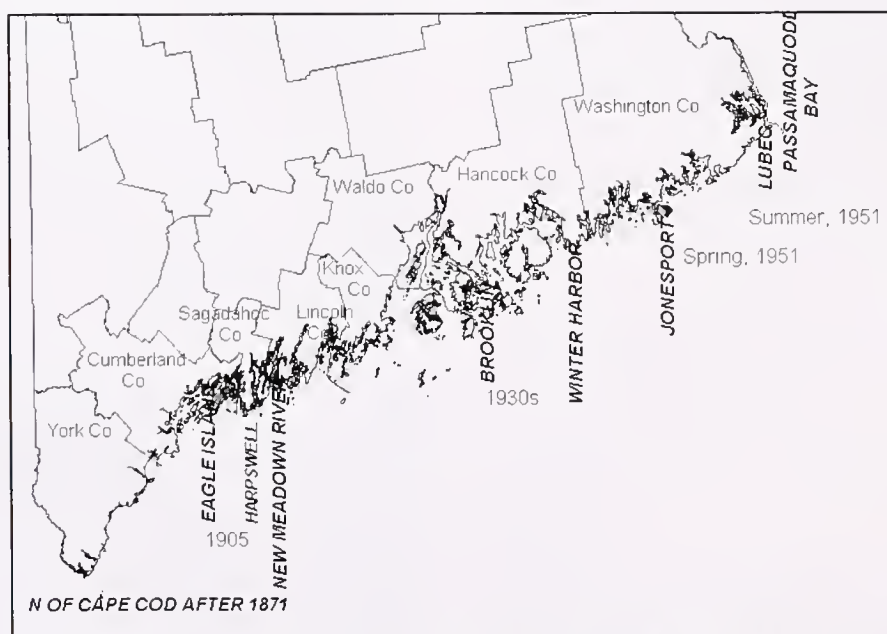

Figure 5. Distribution of the green crab along the Maine coast moving eastward.

TABLE 1.

Green crab sampling between 1953 and 1965 with a standard green crab trap (Welch 1968) except for Perry, Maine where samples are crabs found per man-hour search.

Location	Year of sampling		
	1953–7	1958–9	1960–5
Bocabec River New Brunswick	343	53–41	7.5/trap day
Perry	552		7/man-hour
Lubec	13	16	0/trap day
Jonesport, Cummins Beach	235–500	50	50–6/trap day
Mount Desert I.	255–8	0	0/trap day
Southport, ME	110–670/trap day		

Data—Green Crab Observations 2003–2004

In fall 2003 and winter 2004, two locations in E Maine were sampled with commercial crab traps from October 2003 to January 2004 (Jacques et al. 2004). Trap catch/tide ranged from 11–0/trap/tide at Tidal Falls from October to January and 76–0 trap/tide at Bunkers Harbor during the same period. Although the trap design was different from traps used by DMR in the 1950s, the crab catch at Bunkers Harbor in the fall adjusted to 1.9 tides/day was comparable to catch rates throughout Maine in the 1950s in Table 1. During the same fall–winter, four fishermen bottom dragging in E Maine, reported moderate to numerous live crabs in their traps in the fall, but four of five dragging in the spring found numerous dead green crabs in their hauls after a particularly severe winter with an average water temperature of 2.81°C, which is one of the lowest winter water temperatures in 60 years (See Fig. 8 later).

In laboratory, using crabs caught in the field trial, green crabs were immobilized at 1°C, mortality observed at –3°C with larger crabs dying sooner (–0.036 days survival/mm carapace width, $P < 0.001$) at this temperature (Jacques et al. 2004). The temperature threshold for immobility was lower than the 8°C observed by Atkinson & Parsons (1973), but the temperature threshold for mortality was similar to –2.3°C (Spear 1955a). Laboratory observations of immobility at 1°C corresponded with field observations because no crabs were caught when the water was below this temperature. On the Thames River, temperature was found to be

the only physiochemical variable with a significant effect on green crab abundance (Attrill et al. 1999).

Maine Coastal Water Temperature and Green Crab Abundance

Because S Maine and E Maine clam populations have shown different trends through time (Fig. 2), separate time series of local water temperatures were obtained for each region. Water temperatures for the Eastern Maine Coast/Bay of Fundy were from the Canadian Atlantic Zonal Monitoring Program (AZMP, 2004), which collects data through a network of sampling locations to provide basic information on the physical chemical and biological properties of the Northwest Atlantic continental shelf. The Prince 5 Station is at 44.9°N latitude and 66.8°E longitude, east of Eastport, Maine, records continuous daily average water temperatures and salinity at a depth of 50 m. Average daily temperatures and salinities for monthly time series were obtained for 1924 through the present from the Bedford Marine Institute.

Records of surface water temperature (1905 to the present) in S Maine were obtained from the Maine DMR Laboratory, Boothbay Harbor (BBHR). From 1905 through 1949, three thermometer readings taken from the station wharf were averaged. From 1950, measurements were taken 1.68 m below mean low water with infrequent measurements taken from the inlets of the flowing water tanks. Salinity was not measured. The correlation between the mean annual water temperature at Prince 5 and BBHR between 1941 and 2001 was 0.437 ($P < 0.01$). This correlation between annual water temperature at these two stations is similar to the correlations both within and between years between different regions of the Gulf of Maine surface waters with 15 significant correlations between 0.47 and 0.62 and 30 correlations < 0.46 (Mountain & Manning 1994).

The average of water temperatures for the preceding 4 years was examined to predict clam landings because a temperature effect on either clam growth or clam predators would affect landings for four subsequent years as individuals that are presently juveniles grow to market size. Green crabs preferentially prey on small clams and the effects of green crab predation may not be seen until the older age classes are not replaced (Floyd & Williams 2004). Annual clam landings in S Maine (York, Cumberland, Sagadahoc, Lincoln, Knox and Waldo counties) and average winter water temperature for the preceding 4 years for the months of January, February and March measured at BBHR are in Figure 7. The minimum water temperature generally occurs between calendar days 70 and 80 (Mountain & Manning 1994), which would be when most of the winterkill of green crabs would occur. Figure 8 contains annual clam landings in E Maine (Hancock and Washington Counties) and preceding 4-year winter water temperature measured at Prince 5.

Temperature time series for southern and eastern Maine display a warm period in the early 1950s as previously noted, a cold period through the early to mid 1960s followed by a warming period in the late 1970s (Fig. 7, 8). These variations in water temperature at two locations agree with the decadal scale temperature variations observed for the shelf-wide volume-averaged eastern Scotia Shelf and central Gulf of Maine data for the upper 300 m (Loder et al. 2001). The relatively abrupt winter temperature decreases observed in late 1970s at BBHR and in the late 1980s at Prince 5 were not seen in averaged data for the entire region.

The relationship between winter water temperature and clam abundance differ in E Maine and S Maine (Fig. 7, 8). The corre-

Figure 6. Winter water temperatures (January, February, March) at Boothbay Harbor, Maine.

Figure 7. Clam landings (solid line) in southern and midcoast Maine and average water temperature (dashed line) in January, February and March for the preceding 4 years at Boothbay Harbor.

lation between preceding 4-year water and clam abundance is -0.53 in S Maine and $+0.54$ in E Maine. The colder winter waters in S Maine could cause sufficient green crab winterkill to decrease green crab population size, decrease clam predation and increase subsequent clam landings. As a result, the correlation between winter water temperature (lag up to 4) and clam landings is negative in S Maine ($r = -0.53$).

Eastern Gulf waters do not get as cold as S Gulf waters in the winter because the southwesterly Gulf is less stratified than the eastern Gulf in the winter (Mountain & Manning 1994). Surface waters in winter in E Maine may not usually be cold enough to cause wide spread crab winterkill. The observed effect of warmer winter temperature in E Maine has been to increase landings ($r = +0.54$), possibly caused by a longer growing season for clams and early spring algal bloom. However, extremely cold winters such as that observed in the late 1950s and early 1960s (Fig. 8) could cause high green crab mortality even in eastern Maine. Decreased green crab densities were sampled in eastern Maine during this period (Table 1).

Winter water temperature has been found to impact green crab populations and bivalve predation in other areas. A relationship

Figure 8. Clam landing (solid line) in Eastern Maine (Hancock and Washington Counties) and average water temperature (dashed line) in January, February and March for the preceding 4 years measured at Prince 5.

between winter temperatures and clam sets has been observed in Europe in areas with green crabs. High recruitment of bivalves after severe winters in temperate shallow waters occurs in some areas of the Wadden Sea (Strasser et al. 2003). Although there are numerous possible explanations for increased larval recruitment after severe winters, reduced numbers of larvae of both *Mya* and *Carcinus* were observed after the winter of 1995/6 "supporting the hypothesis that reduced epibenthic predation is an important factor in high bivalve recruitment after severe winters" rather than enhanced *Mya* larval supply (Strasser & Guenther 2001).

CONCLUSION

Softshell landings have dramatically declined in Maine over the past 25 y because of low productivity of clam flats in Eastern Maine. Low productivity of clam flats would be affected by:

- high fishing pressure on diminished stocks;
- heavy predation by green crab populations not limited by winterkill in the E Gulf.

Density of clam sets would be decreased by:

- harvesting stocks previously protected by pollution closures.
- Dispersion of clam larvae away from their flats of origin by strong tidal currents.

Sporadic heavy sets of juvenile clams do occur. Epifanio and Garvine (2001) describe north winds, Ekman flow and the resulting shoreward downwelling moving the blue crab, *Callinectes sapidus* (Rathbun) megalopae larvae inshore toward settlement sites in bays along midAtlantic states. Clam pediveligers that move to the surface waters could likewise be moved inshore. The prevailing wind direction in August through November in Portland, ME is from the NNW to NW (National Climatic Data Center, 1998; Fefer & Schettig 1980) and would produce favorable shoreward Ekman flows. The unpredictable occurrence of favorable winds on surface patches of pediveliger larvae would result in settlement events.

The extension of the range of the green crab up the coast of New England has negatively impacted clam populations particularly in areas such as E Maine where warmer winter water temperatures may have limited winterkill of green crabs. Change in the Gulf of Maine Sea Surface temperature (SST) over 120 years was estimated from a NOAA Extended Reconstructed SST data provided by the NOAA-CIRES Climate Diagnostics Center (Clean Air-Cool Planet 2005). The change in mean annual SST between 1880 and 2001 was estimated to be 0.6°C and the change in mean winter temperature over the same period was 0.2°C . Green crab sampling should be used to determine effect of crab populations on clam stocks. If crab populations are determined to be one of the factors limiting reestablishment of clam stocks, techniques for crab control should be developed and implemented (Walton 2000).

Management practices over the past century have not maintained a consistent clam fishery (Fig. 1) and present management practices such as a minimum harvest size have not been successful at reestablishing clam populations in E Maine (Fig. 2).

Management strategies should be implemented to increase harvests and sets:

- Clam mariculture could be used to produce both marketable clams and sets to repopulate local flats. Coastal areas could be managed to produce harvests from both cultivated and wild clams while producing sufficient larvae for a natural set.
- Rotational digging of flats should be evaluated to maintain

breeding populations while allowing adults to grow without breakage and reburial from premature digging. Areas that are dug in the rotation could be repopulated with a natural set, hatchery produced seed or seed from areas with high density sets.

Regional coordination of restoration effort may be required because local spawn may not become the local set.

INITIAL RECRUITMENT AND GROWTH OF SURFCLAMS (*SPISULA SOLIDISSIMA* DILLWYN) ON THE INNER CONTINENTAL SHELF OF NEW JERSEY

HONGGUANG MA,* JUDITH P. GRASSLE AND JEANINE M. ROSARIO

Institute of Marine and Coastal Sciences, Rutgers, The State University of New Jersey, 71 Dudley Road, New Brunswick, New Jersey 08901

ABSTRACT Surfclam (*Spisula solidissima* Dillwyn) larval settlement and the initial growth of recruits were studied on the inner shelf of New Jersey. Initial recruitment was measured by taking weekly benthic core samples during the summer settling season, and larval supply was characterized using meroplankton samples taken every four hours in July. The temporal variation in recruitment at two inshore stations (12-m depth) was linked to larval supply from the water column, and spatial differences (inshore vs. offshore) in recruitment also appeared to be related to larval supply. Spatial and temporal variation in larval concentrations was associated with wind-driven cross-shelf circulation. Contrasting recruitment patterns between the two inshore stations could not be explained by larval supply alone and were likely affected by near-bottom flows. Growth rates of initial surfclam recruits (with initial shell lengths <360 μm) were estimated to be 10–20 $\mu\text{m d}^{-1}$, and the growth rates of individuals >360 μm shell length were 25–50 $\mu\text{m d}^{-1}$. This study provides realistic field estimates of early growth rates of surfclams and further evidence of the relationship between upwelling/downwelling events and surfclam larval supply and initial recruitment on the inner continental shelf.

KEY WORDS: surfclam larvae, settlement, post-larval growth, recruitment

INTRODUCTION

The surfclam (*Spisula solidissima* Dillwyn) lives in a zone from the shallow subtidal out to depths of about 60 m, and ranges from the Gulf of St. Lawrence, Canada, south to North Carolina (Merrill & Ropes 1969). It is an important commercial species in the Mid-Atlantic Bight (NOAA/NMFS 2003). Surfclam populations are characterized by great year-to-year variation in recruitment success, especially in inshore areas (Murawski & Serchuk 1989, Weinberg 1993, 1999, Chintala & Grassle 2001). Pre- and postsettlement processes, both physical and biological, are likely responsible for spatial and temporal variation in recruitment success.

To understand factors affecting inshore surfclam larval settlement and initial recruitment a study was initiated at a Long-term Ecosystem Observatory at 15-m depth (LEO-15) off southern New Jersey in 1993. The study area lies within one of the recurrent upwelling centers on the New Jersey coast (Glenn et al. 2004) and is characterized by episodic summer upwelling/downwelling events, which appear to be related to the arrival of high concentrations of surfclam larvae. Studies on larval surfclam supply with respect to these events (Ma & Grassle 2004, Ma 2005, Ma et al. 2006), larval settlement (Snelgrove et al. 1999, 2001, Weissberger & Grassle 2003, Ma 2005) and recruitment during the first year of life (Weissberger & Grassle 2003) form the background for the present study. All of these observations and experiments were focused on larvae spawned by inshore surfclam populations that experience rapidly warming temperatures in the late spring (Starypan 1976). At LEO-15, benthic studies (1993–2004) show that larval settlement from this inshore spawning population occurs chiefly in late June and July, with some markedly reduced settlement in August in some years (Weissberger & Grassle 2003, Snelgrove et al., 1999, 2001, Grassle unpubl. data). Offshore surfclams living under the influence of the Middle Atlantic cold pool do not spawn until the thermocline breaks down in the late summer or early fall (or in some instances when there is storm mixing). It is

likely that these larvae are widely dispersed on the continental shelf in the fall and winter months, and we have evidence of surfclam larvae being present in the plankton at LEO-15 as late as February of the following year (Gregg, Tucker & Grassle, unpubl. data).

This study focused on benthic sampling at three LEO-15 stations during the expected peak in surfclam settlement in July 1998, together with frequent near-bottom sampling of surfclam larvae at the same stations. The year 1998 was chosen in part because initial surfclam recruitment was relatively high for the first time since 1993 (Weissberger & Grassle 2003). The primary goal was to identify the arrival of high concentrations of competent surfclam larvae, and to follow the growth of the consequent pulses of juvenile surfclams in the benthic samples at frequent enough intervals to provide estimates of growth rate in the earliest postsettlement stages (i.e., from a maximum shell length at settlement of approximately 290 μm). One goal of our study was to describe surfclam growth during the earliest postsettlement stages, because it is likely that these growth rates will affect whether the juveniles find a size refuge from predation.

MATERIALS AND METHODS

Study Site

The study site was located in the vicinity of Beach Haven Ridge (Fig. 1). Samples were taken from three stations, two inshore (Sta. 9 and C at 12 m depth) and one offshore (Sta. C2 at 20 m depth). Sta. 9 (39°27.69'N, 74°15.81'W) is on the inshore flank of the ridge with a coarse sand bottom, and Sta. C (39°27.85'N, 74°15.11'W) is on the offshore flank of the ridge with a finer sand bottom (Craghan 1995). Sta. C is about 1 km seaward of Sta. 9. Sta. C2 (39°23.24'N, 74°12.75'W) is a sandy site, 8 km offshore from Sta. 9. At Sta. 9 and C bottom temperatures during the summer vary greatly during alternating periods of upwelling and downwelling, whereas the bottom temperature at Sta. C2 rarely exceeds 12°C during the summer months, except for occasional storm mixing (Glenn et al. 2004, Ma & Grassle 2004).

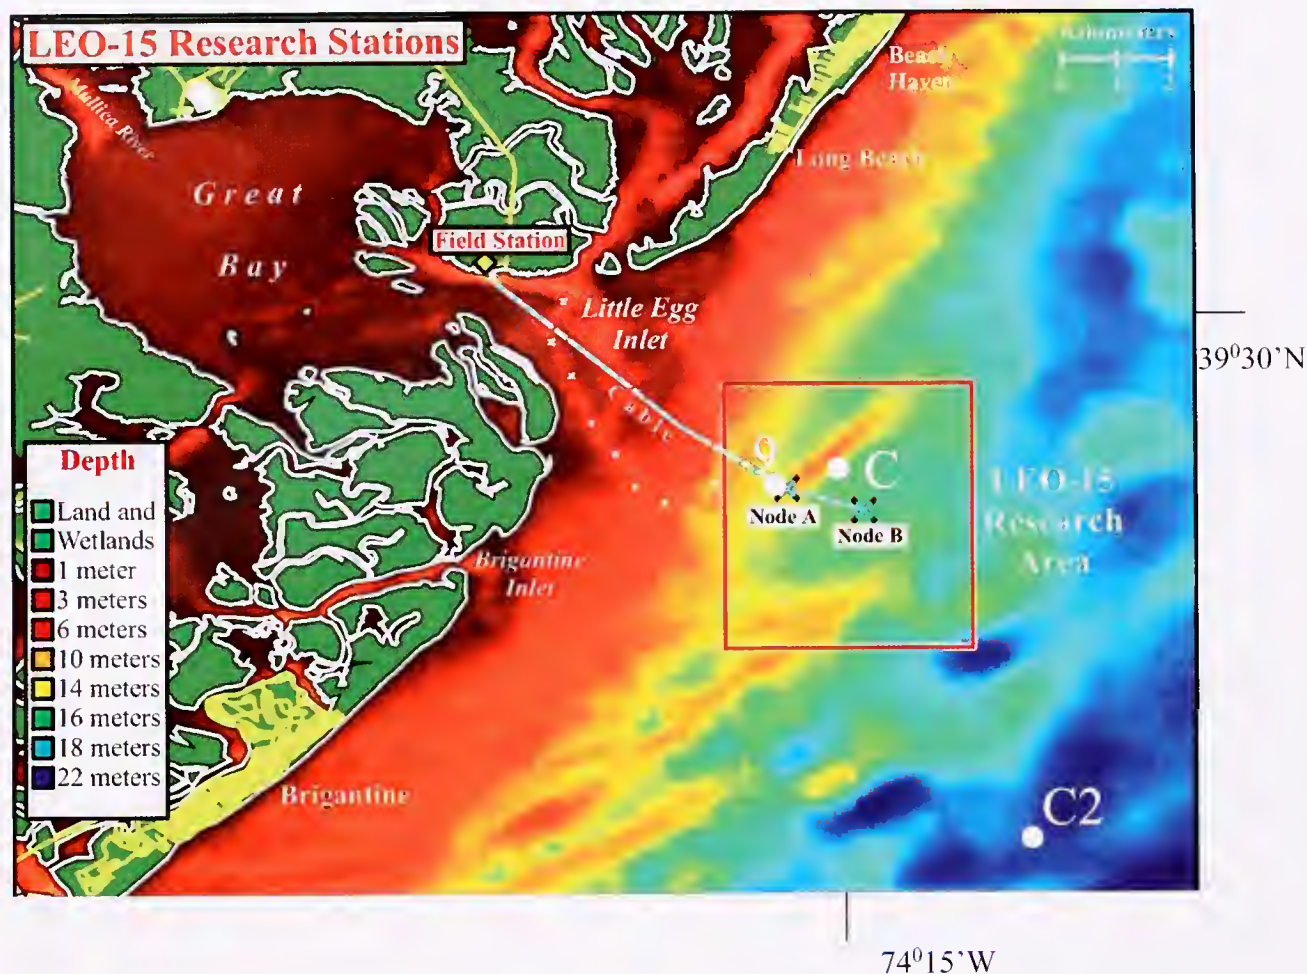

Figure 1. Bathymetric map of LEO-15 and locations of sampling stations (modified from Ma and Grassle 2004).

Physical Data

Alongshore wind (SW/NE) and water temperature 1 m above the bottom were used to track upwelling and downwelling events. Wind data were from the Rutgers University Marine Field Station meteorological tower, where wind intensities were recorded 10 m above the ground. Water temperatures were recorded by thermistors on the zooplankton pump housing and on the pump frame.

Surfclam Larval Sampling

Three Moored, Automated, Serial, Zooplankton Pumps (MASZPs, Doherty & Butman 1990) were deployed at Sta. 9 and C from July 6–27 and at Sta. C2 from July 11–14, 1998. Samples (250 l) were taken automatically every 4 h, 1 m above the bottom (see Ma & Grassle 2004 for further details). The samples were filtered through 100- μ m mesh and organisms trapped on the filter were wound onto a take-up spool in a fixative compartment with 10% buffered formaldehyde. The take-up spool was retrieved after a 3-wk deployment. The meshes were cut into individual pieces corresponding to each sample and transferred to 70% ethanol with Rose Bengal. Each sample (no splitting) was examined under a dissecting microscope. Bivalve larvae with shell length >150 μ m were identified (Ma & Grassle 2004). In samples with high concentrations of surfclam larvae, shell lengths for up to 100 individuals were measured using an ocular micrometer to judge the readiness of the larvae to settle.

Benthic Sampling

Divers took 8 benthic core samples (7-cm diameter corer, area 38.5 cm²) at Sta. 9, C, and C2 at approximately weekly intervals in July, then at increasing intervals to monthly from September to December 1998. At Sta. 9 and C2 (rippled bottom) four pairs of samples (ripple trough and adjacent crest) were taken, with about 1 m between pairs. At Sta. C (no ripples) paired samples were taken at approximately the same intervals. Core samples were kept on ice for several hours until they were preserved in 95% ethanol and subsequently stained with Rose Bengal. The samples were sieved over a 106- μ m sieve and sorted under a dissecting microscope. When there were high concentrations of surfclams at Sta. C, a total of 200 individuals (100 haphazardly taken from each of two replicate cores) were measured. At Sta. 9, individuals from 6–8 replicate cores were combined to obtain 200 individuals for each sampling date in July. Initial surfclam recruitment at C2 was too low to achieve comparable sample sizes for measurement. Surfclam images were captured using a color camera linking a Zeiss dissecting microscope to a Macintosh computer and the IMAGE program (calibrated with a micrometer) was used to measure shell lengths.

Surfclam larvae settle at shell lengths from 230–290 μ m (Snelgrove et al., 1998), and surfclam juveniles were observed to increase in shell length ~ 10 μ m per day in the laboratory (J. Bell, unpublished data). In the present study surfclams with

shell lengths $<360\text{ }\mu\text{m}$ were considered to have settled recently, probably within the previous week (a time interval equivalent to the benthic sampling intervals in July). This cutoff assumed an upper limit for settling larvae of $290\text{ }\mu\text{m}$ and 7 days of growth at $10\text{ }\mu\text{m d}^{-1}$. The accumulation of surfclam individuals $<360\text{ }\mu\text{m}$ was used to estimate initial recruitment with the recognition that this estimation would incorporate early postsettlement mortality.

Data Analysis

A Computer-Assisted Analysis of Mixtures (C.A.MAN, Böhning et al. 1992) was used to find the number of cohorts and the mean shell lengths for each cohort. On each date/station combination, shell distributions were fitted to different numbers of cohorts. In general, the greater the number of cohorts included for fitting, the larger the likelihood of the fitting. Decisions on choosing the number of cohorts were based on likelihood adjusted by the number of estimated parameters (i.e., Akaike's Information Criterion, Weissberger & Grassle 2003) and visual fitting with the raw data in histograms. The initial values (mean and weight of each cohort) were estimated from raw data, and C.A.MAN calculated the maximum likelihood estimates for these parameters. Growth was estimated by following the cohorts over time. Urban (2002) pointed out that bivalve larvae and postlarvae grow linearly or exponentially whereas adult growth is asymptotic. Growth rates for the surfclams were calculated assuming both linear ($L_{t+\Delta t} = L_t + r \times \Delta t$) and exponential growth ($L_{t+\Delta t} = L_t \times e^{r\Delta t}$).

Analysis of variance was carried out for densities of initial

surfclam recruits ($<360\text{-}\mu\text{m}$ shell length) in July using a general linear model (GLM) in SAS. Dates and stations were fixed factors. The GLM procedure was used instead of ANOVA because of the variable number of replicate samples (6–8) completed for each station/date combination (Cody & Smith 1997). The data for number of surfclams were logarithmically transformed to remove heterogeneity in variance. Because of the unbalanced design, standard multiple comparison tests (such as Tukey, Duncan, or SNK tests) were not used (Cody & Smith 1997). Instead, multiple *t*-tests with an overall significance level $\alpha (=k \times \alpha') = 0.05$ were used, where *k* is the number of comparisons and α' is the significant level for individual *t*-tests (Bonferroni method).

RESULTS

Physical Conditions and Surfclam Larval Concentrations in the Water Column, July 1998

Downwelling winds were interspersed with episodic upwelling winds before July 12, and bottom temperatures at the two inshore stations, Sta. 9 and C, varied between 13°C and 17°C until July 10 when temperatures increased to around 20°C from July 11–13 (Fig. 2). Upwelling winds began July 12 and persisted until late on July 24 when downwelling winds blew for 2 d. During the sustained upwelling wind, bottom temperatures were $<13^\circ\text{C}$ for >10 days. Temperatures increased near the end of the larval sampling period during the 2 d of downwelling winds. At offshore Sta. C2, bottom temperatures remained $<12^\circ\text{C}$ throughout July (Fig. 2).

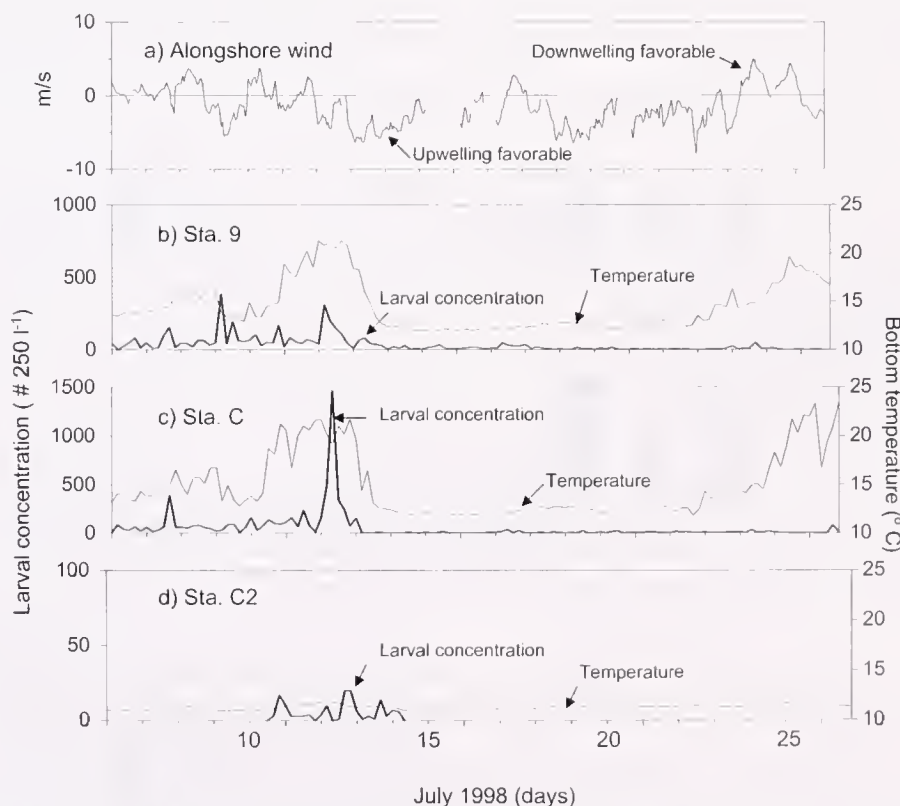

Figure 2. Alongshore winds (a) and surfclam larval concentrations and bottom temperatures at (b) Sta. 9, (c) C, and (d) C2 in July 1998. Alongshore winds are hourly averaged wind intensities (10 m above the ground) from the southwest (negative, upwelling favorable) or from northeast (positive, downwelling favorable). Note scale differences in larval concentrations. Larval data for Sta. C2 were only available for July 11–14.

TABLE 1.

Shell length distribution of surfclams in plankton samples when high concentrations were present (bivalve larvae $>150\ \mu\text{m}$ were identified). Laboratory studies (Snelgrove et al. 1998) indicate that larvae are ready to settle at shell lengths (SL) $230\text{--}290\ \mu\text{m}$, so larvae $<230\ \mu\text{m}$ SL were probably not competent, and some individuals $>320\ \mu\text{m}$ SL were likely to be resuspended juveniles.

Station, Date (hours)	$<230\ \mu\text{m}$	$230\text{--}290\ \mu\text{m}$	$290\text{--}320\ \mu\text{m}$	$>320\ \mu\text{m}$	Total

Sta. C					
July 8 (7:00)	15	39	41	5	100
July 10 (15:00)	0	78	20	2	100
July 11 (19:00)	0	74	13	13	100
July 12 (3:00)	18	70	9	3	100
July 12 (19:00)	3	79	17	1	100
July 12 (23:00)	11	67	20	2	100
July 13 (3:00)	13	76	11	0	100
July 13 (7:00)	20	74	4	2	100

Surfclam larval concentrations were relatively high and variable before July 13 at the two inshore stations (Fig. 2). At Sta. C there was a sharp peak in surfclam larval concentration on July 12–13, coinciding with the presence of relatively low salinity wa-

ter (Ma and Grassle 2004). Surfclam larval concentrations were low ($0\text{--}46\ \text{ind. } 250\ \text{l}^{-1}$) inshore after July 13 during the sustained upwelling. At offshore Sta. C2, surfclam larval concentrations were low ($\leq 20\ \text{larvae } 250\ \text{l}^{-1}$) from July 11–14 at the time when high concentrations were found inshore.

Except for the magnitude of the peak in larval surfclam concentration at Sta. C on July 12–13, the integrated larval supplies to Sta. 9 and C during July were very similar. Larvae present in the water column at that time were mostly of a size suggesting that they were competent to settle based on laboratory culture studies (Table 1). In Table 1, shell length distributions for surfclams in plankton samples where they were abundant are shown on 5 d between July 8 and 13. There was a small percentage of probable precompetent larvae ($<230\ \mu\text{m}$), 30–80% competent larvae ($230\text{--}290\ \mu\text{m}$) and a small fraction of juvenile surfclams $>320\text{-}\mu\text{m}$ shell length that had been resuspended from the bottom. This leaves a sizeable proportion (5–40% in the different samples) ranging in shell length from $290\text{--}320\ \mu\text{m}$, which probably included both larvae and recently metamorphosed individuals.

Abundances of Initial Surfclam Recruits

At inshore Sta. 9, total surfclam densities were $>20\ \text{ind. core}^{-1}$ in July and $<5\ \text{ind. core}^{-1}$ in August and September (Fig. 3). Relatively high surfclam densities appeared again in November with the recruitment of fall-spawned larvae in October and November. This October–November pulse was observed at all three stations. At Sta. C, surfclam densities were very high ($>200\ \text{ind. core}^{-1}$) in July. At offshore Sta. C2, surfclam densities were <10

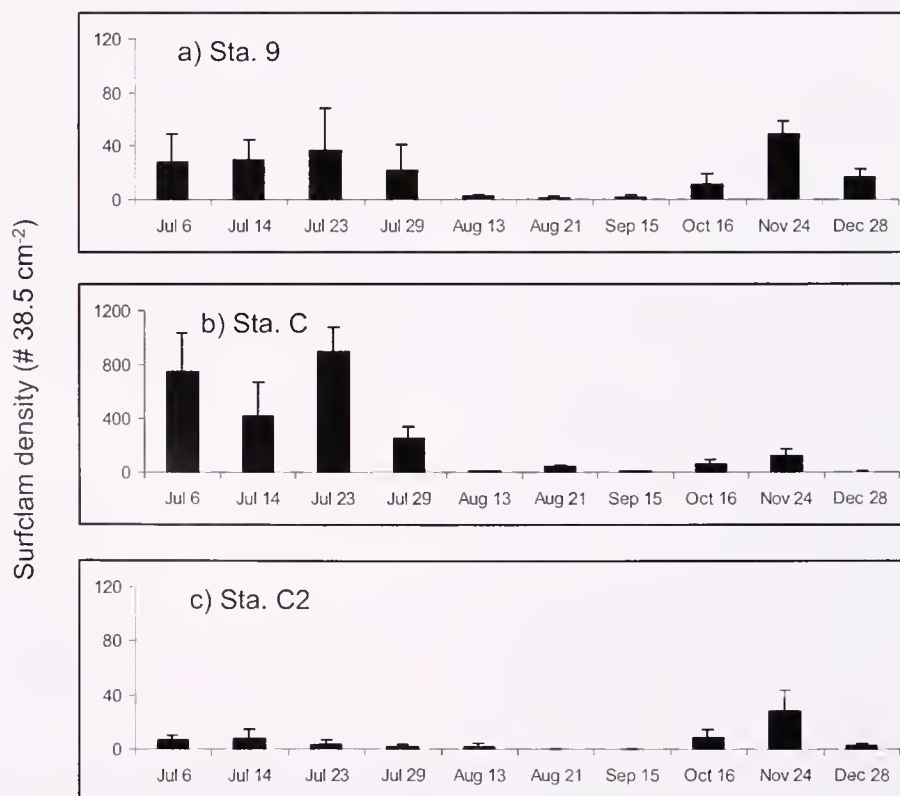

Figure 3. Mean (\pm SD) number of surfclams core^{-1} ($38.5\ \text{cm}^2$) in samples at three LEO-15 stations from July to December 1998 (a) Sta. 9, (b) Sta. C, (c) Sta. C2. Note difference in scales of y-axes with surfclams being an order of magnitude more abundant at Sta. C. Temporal patterns in abundance were similar among the three stations.

ind core⁻¹ throughout the summer and fall and about triple that in November with the fall recruitment (Fig. 3).

Analysis of variance for initial surfclam recruits (referring to individuals with shell lengths <360 μm) in July showed that sampling date, stations, and the interaction between date and station had significant effects on densities (Table 2, Fig. 4). The pooled initial recruits from the three stations were significantly more abundant on July 6 and July 14. Initial recruitment was highest at Sta. C and lowest at Sta. C2. At Sta. C and C2, the number of initial recruits was significantly higher on July 6 and 14 than on July 23 and July 29 (Table 2). At Sta. 9, initial recruitment was significantly higher on July 6 and 14 and lowest on July 29.

The initial surfclam recruits present in the benthos on July 14 at all three stations were a likely consequence of the competent larvae present in the water column in the previous sampling interval (Fig. 4). Initial surfclam recruitment at each of the stations was roughly proportional to larval supply, with the highest larval supply and recruitment at Sta. C and the lowest at Sta. C2. However, the difference in initial recruitment between Sta. 9 and C was comparatively great (~10 times) compared with larval supplies to the two inshore stations. The average larval surfclam concentrations during July 6–14 were 79 ind. 250 l⁻¹ at Sta. 9 and 119 ind. 250 l⁻¹ at Sta. C. Low abundance of initial surfclam recruits in the benthos at all three stations at the end of July was correlated with low larval supply in the last two July sampling intervals.

Short-term Growth of Surfclams

Three modes were identified by the C.A.MAN procedure for the surfclams sampled on July 6 at Sta. 9 and C and two modes for the other three dates in July (Fig. 5). Growth rates were calculated when advancement of modes with time could be established (lines shown on Fig. 5). Only modes with weights (proportions) >0.2 (20%) were included for growth estimation (the weights of all modes at one date/station combination add up to 1). Both linear ($\mu\text{m d}^{-1}$) and exponential (d^{-1}) growth rates were calculated. Two estimates were made at Sta. 9 and six at Sta. C. (Fig. 5 and Fig. 6). Only the results using the linear growth model are shown. Linear growth rates for initial surfclam recruits (<360- μm shell length)

ranged from 9.7–18.1 $\mu\text{m d}^{-1}$. Exponential growth rates for the same individuals ranged from 0.029–0.052 d^{-1} . Linear growth rates of individuals >360- μm shell length ranged from 25.0–51.6 $\mu\text{m d}^{-1}$ (0.021–0.081 d^{-1} for exponential growth rates). There were too few surfclam recruits at Sta. C2 to permit an analysis of growth, and they ranged mainly from 260–960 μm shell length in July (more similar to Sta. 9).

The surfclams recruiting at Sta. C in the July 6–14 interval did not appear as a separate mode on July 14 (Fig. 5). The first mode on July 14 at Sta. C was likely composed of survivors from the first mode on July 6 and larvae settling during July 6–14. This could have resulted in an underestimate of the growth rates of surfclams in the first mode on July 6. Visually selecting the shell length with the highest frequency (highest bar in Fig. 5) on July 14 as the “mode” for survivors from July 6 would increase the linear growth-rate estimate by only 4 $\mu\text{m d}^{-1}$.

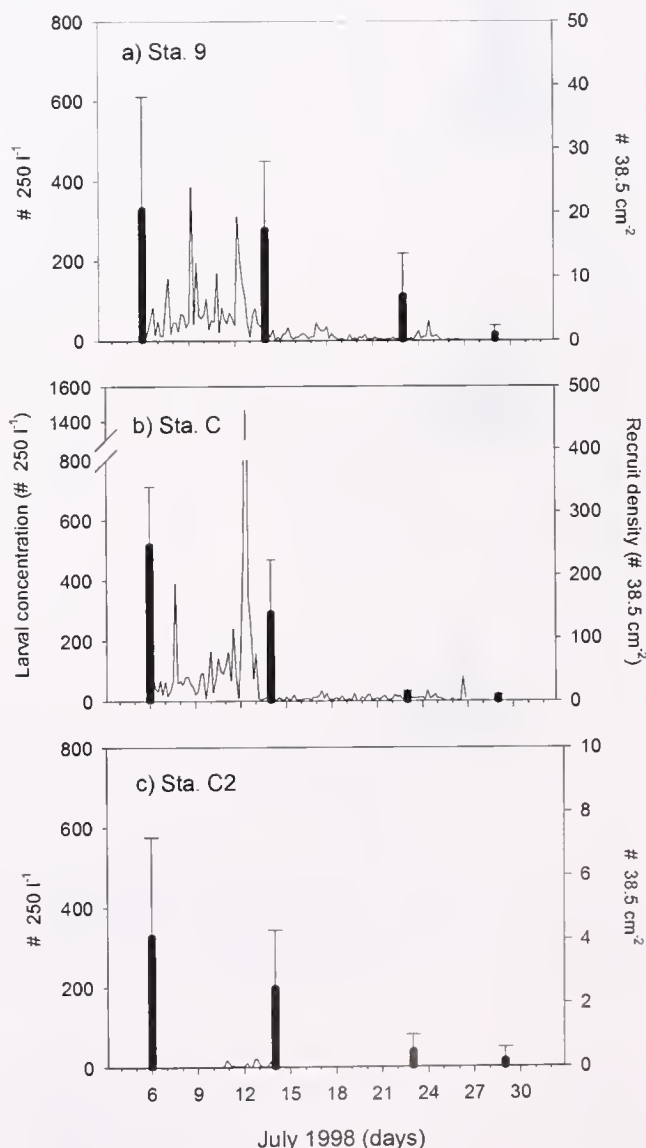

Figure 4. Larval concentration (# 250 l⁻¹, lines) and density + SD (# 38.5 cm⁻², bars) of initial surfclam recruits (<360 μm shell length) in July 1998 (a) Sta. 9, (b) Sta. C, (c) Sta. C2. Note differences in scales on y-axes for surfclam densities in benthic samples and larval data available from July 6–27 at Sta. 9 & C and from July 11–14 at Sta. C2.

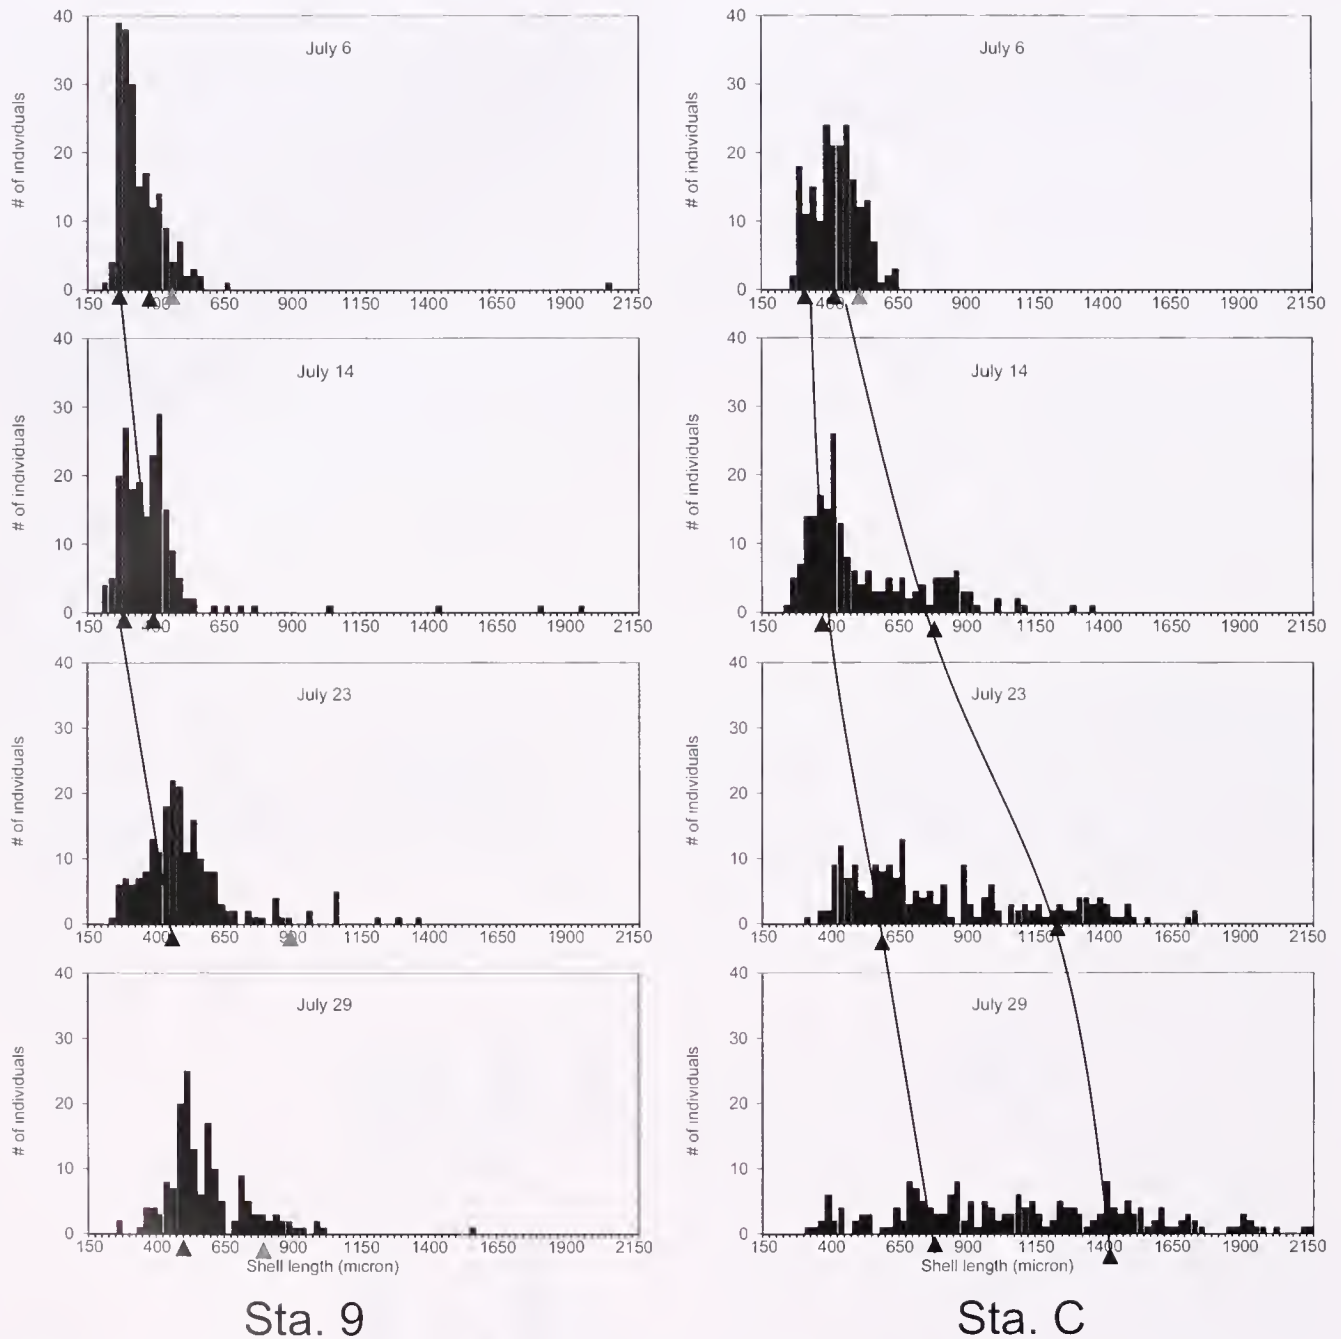

Figure 5. Shell length (SL) distribution of surfelams in July 1998 at Sta. 9 and C ($n = 200$ for all panels except Sta. 9, July 29 [$n = 162$]). Dark arrows indicate mean SL of cohorts identified by C.A.MAN (Böhning et al. 1992); light arrows have weights <0.2 (total weights are 1.0 on each panel). Lines represent advancements of modes with time. At Sta. 9, advancements of modes were less clear because of lack of accumulation of larger juvenile surfelams, and only two advancements were established. See Figure 2 for temperatures and upwelling/downwelling conditions during July 6–14, July 14–23, and July 23–29.

The intersampling growth periods at Sta. 9 and C in July provided a contrast in temperature regimes: interval 1 (July 6–14) was characterized by temperatures varying from 13°C to 22°C, including some very rapid increases and decreases; interval 2 (July 14–23) was characterized by uniformly low temperatures (12°C to 13°C) during upwelling; interval 3 (July 23–29) was more like interval 1, with temperatures varying from 12°C to 23°C at Sta. C and 13°C to 20°C at Sta. 9 (Fig. 1). There appeared to be no relationship between growth rates and the prevailing temperature regimen (Fig. 6).

DISCUSSION

There was good correspondence between the timing of the highest initial surfelam recruitment and surfelam larval supply at the two inshore stations in July 1998. There was also a rough correlation at all three stations between the magnitude of larval surfelam supply during the period July 6–14 and the abundance of initial surfelam recruits, with Sta. C having the highest larval supply and the highest abundance of recruits and Sta. C2 the least. This relationship between surfelam larval supply and initial re-

Figure 6. Linear growth rates ($\mu\text{m d}^{-1}$, open bars) of surfclams calculated from C.A.MAN analysis of shell length distributions of surfclam juveniles at Sta. 9 and Sta. C on four dates in July. Mean bottom temperatures corresponding with growth-rate estimates during intervals July 6–14, July 14–23, and July 23–29 (marked 1, 2 and 3) are represented with filled triangles for Sta. 9 and filled squares for Sta. C.

cruitment had previously been demonstrated experimentally at the same three stations in 1997 (Ma 2005), although in that year the correlation was significant for Sta. C and C2 but not for Sta. 9. At Sta. 9 the abundance of initial surfclam recruits was less than would have been expected given the similarity in larval supply between Sta. 9 and C, the two inshore stations, which are only one kilometer apart. Ma (2005) has hypothesized that the generally lower initial surfclam recruitment at Sta. 9 compared with Sta. C over several years (Weissberger & Grassle 2003, Quijon & Grassle, in prep.) could be a consequence of stronger near-bottom flows at Sta. 9, especially during storms. These flows could inhibit surfclam larval settlement and/or be responsible for resuspending sediment and winnowing initial recruits out of the sediment and depositing them on the crest and seaward side of Beach Haven Ridge. This hypothesis is partly supported by the difference in sediment grain size between Sta. 9 and C (Craghan 1995), namely coarser sediment characterizes Sta. 9, and it may also explain the great difference (\sim one order of magnitude) in initial surfclam recruitment between the two inshore stations during downwelling in July 1998 in the face of relatively similar integrated larval supplies.

Based on shell lengths, many of the surfclams present in core samples inshore on July 6 settled in June, probably in association with several upwelling/downwelling periods during that month, namely relaxation or downwelling on June 9–12 and June 17–30. After the initial larval settlement pulses in June and early July, a sharp decline in surfclam densities was observed, and there were few or no individuals remaining in the sediments in August and September. Assuming that there was no new settlement and the decline in density was caused by mortality only, the estimated mortalities (z) using an exponential survival equation $N_{t+\Delta t} = N_t \times e^{-z\Delta t}$ (e.g., Hilborn & Walters 1992) were 0.21–0.22 d^{-1} from July 23–29 and from July 29 to August 13. The absence of larval settlement was reflected in the very low numbers of surfclams with shell lengths $<360 \mu\text{m}$ on July 23 (immediately after upwelling), on July 29, and August 13, especially at Sta. C. However, the estimated mortalities could also be affected by resuspension and bedload transport of surfclam recruits to or from other locations.

The mortality of juvenile surfclams was likely caused by multiple impacts of numerous predator species. They include several

species of brachyuran crabs (Stehlik 1993), hermit crabs (Newby 2005), crangonid shrimp (Viscido 1994, Viscido et al. 1997), naticid snails (Weissberger & Grassle 2003, Quijon & Grassle, in prep.) and starfish (Weissberger & Grassle 2003). It is likely that the relative importance of the predators varies from year to year depending on the timing of settlement and initial abundance of the juvenile stages that prey on the smallest surfclams. For example, the 1993 summer year class of surfclams was preyed on by the naticids *Neverita duplicata* and *Euspira heros* and the sea star *Asterias forbesi*. By virtue of the high density of recently settled sea stars beginning in July of that year at Sta. 9 and C, and their high feeding rates, their impacts on juvenile surfclam density were estimated to be much higher ($4,500 \text{ surfclams m}^{-2} \text{ d}^{-1}$) than the impacts of naticid predation ($90 \text{ surfclams m}^{-2} \text{ d}^{-1}$) (Weissberger & Grassle 2003). In 1998 no sea stars were observed in the benthic samples so it is likely that the declining densities in August and September in the present study were a combination of crustacean and naticid predation (Quijon & Grassle, in prep.).

Total surfclam densities increased in October and November at all three stations. More than 80% of individuals in November at the two inshore stations were $<430 \mu\text{m}$ shell length, and $>50\%$ were $<430 \mu\text{m}$ shell length at the offshore station. It is highly likely that these increases in densities were caused by new larval settlement and recruitment in the fall, the result of spawning by surfclams living below the summer thermocline (Tarnowski 1982, Wagner 1984, Weissberger & Grassle 2003, Ma & Grassle 2004). When the thermocline breaks down, warmer water reaches the bottom, inducing the offshore clams to spawn. Pulses of high larval surfclam concentrations were previously observed in the water column in the fall (September to October) at a southern New Jersey site within 80 km of the LEO-15 research area (Haskin et al. 1981, Tarnowski 1982). We also have unpublished data showing that fall-spawned surfclam larvae may persist in the water column at LEO-15 into December and even the following February (Gregg, Tucker, & Grassle unpubl. data), though whether the larvae found in the plankton in February settle and metamorphose successfully is unknown.

Urban (2002) evaluated the applicability of several standard models to the growth of different developmental stages of pearl oysters, including larvae, plantigrades, postlarvae, and juveniles. Like previous authors he concluded that the larvae and plantigrades grow linearly or exponentially (e.g., Bayne 1965, Beaumont & Budd 1982, Rose & Baker 1994). The linear growth rates for initial surfclam recruits ($<360 \mu\text{m}$) in our study were 9.7–18.1 $\mu\text{m d}^{-1}$. Subsequent growth rates of juveniles $>360 \mu\text{m}$ shell length were somewhat higher (25.0–51.6 $\mu\text{m d}^{-1}$). These growth rates were comparable to those estimated by Weissberger and Grassle (2003) for clams settling in similar densities in 1993 (14.6–63.5 $\mu\text{m d}^{-1}$). No clear trend of increased linear growth rate with increased initial size (an indication of exponential growth) was observed in our study. The lower growth rates for the initial surfclam recruits ($<360 \mu\text{m}$) may be a result of the period of time between loss of the larval velum and formation of labial palps at metamorphosis and development of functional suspension-feeding structures (fused siphons and gills). This has not been examined directly in *Spisula solidissima*, but in other bivalves these developmental processes may take one to several days depending on temperature (e.g., Bayne 1971, Reid et al. 1992).

Plotting 1993 growth rates directly against bottom temperature, Weissberger and Grassle (2003) found some correlation up until September. In the present study there was no evidence of any growth rate/temperature correlation for the smallest clams in July

1998. Of course many factors may affect the growth of bivalve recruits, not just temperature. They include population density and the availability of appropriate food. At different intertidal sites in Maine, surfclam juveniles grew faster at sites with warmer water temperatures and higher levels of chlorophyll *a* (Davis et al. 1997). Because upwelling at the LEO-15 sites is associated with high POC and chlorophyll *a* values (Glenn et al. 2004), it is possible that growth of recently settled surfclams during the July upwelling (July 14–23) was enhanced by an increased flux of food particles to the bottom, thus counterbalancing the negative effects of low prevailing temperatures on growth. The LEO-15 research area also represents one of the recurrent hypoxic nodes associated with summer upwelling along the New Jersey coast, but the potential effects of high variance in bottom water O₂ concentrations during July (Boehme et al. 1998) on both juvenile surfclam growth and mortality have not been studied.

Other studies that have examined early growth of surfclams have generally been conducted over much longer time intervals and in some cases under relatively nonnatural field conditions (e.g., Belding 1910, Starypan 1976, Jones et al., 1978), and the initial lengths of the surfclams were at least several millimeters. In a study of surfclams using the growth bands laid down in the shell, Chintala and Grassle (2001) found that surfclams in the inner shelf environment off New Jersey generally reached shell lengths of 10.3–22.0 mm when the first band was laid down, with no significant differences in mean shell length among nine nearshore zones. Although these shell lengths are considerably less than in some other studies (e.g., Jones et al. 1983), they are consistent with previous estimates for the LEO-15 area, namely that surfclams settling in July 1993 reached a maximum shell length of 16.0 mm by December (Weissberger & Grassle 2003).

One potential complication for field studies of bivalve growth rates using modal length frequency analyses is that size-selective predation may effectively remove particular size classes. There was some suggestion that naticid predators could have selectively removed surfclams 2–5 mm in shell length during the late summer and fall in 1993, and that *Asterias forbesi* might have targeted

clams 5–12 mm in length in October and November of the same year (Weissberger & Grassle 2003). The effects of size-selection by small crustacean predators of surfclams in the LEO-15 research area remain largely unstudied. In late July 1998, there were many fewer surfclams >1,000- μ m shell length at Sta. 9 than at Sta. C (Fig. 5). This may be an example of initial predator swamping at Sta. C where juvenile surfclams were an order of magnitude more abundant than at Sta. 9 in early July. This would allow some individuals to find a size refuge from predators preying selectively on the smallest individuals.

This study has provided further evidence of the close relationship between upwelling/downwelling events in June and July with surfclam larval supply and initial recruitment in June and July in the inner shelf environment. In addition, the study has provided realistic field estimates of early growth rates under both upwelling and downwelling conditions. Analyses of length frequency distributions and abundances of juvenile surfclams have provided further estimates of the limits on early growth in the nearshore environment and of the probable impacts of the many surfclam predators. Such knowledge is important to the understanding of surfclam recruitment processes and to management of the surfclam fishery in the Mid-Atlantic Bight. Potentially, this kind of information can have implications for shellfish species in other geographic regions.

ACKNOWLEDGMENTS

The authors thank Rose Petrecca and the IMCS diving team for collecting benthic core samples and for deploying the moored zooplankton pumps. Cheryl Ann Zimmer kindly loaned the zooplankton pumps. Amy Stawicki helped sort the benthic core samples and measure the surfclams, and Alex Figueroa helped sort zooplankton samples. Eric Weissberger provided advice on the use of statistical algorithms in C.A.MAN. Pedro Quijon shared the data for surfclam shell lengths in 1998 and provided helpful comments on an early draft. Comments from anonymous reviewers improved the manuscript. This study was supported by a NOAA/NURP grant.

VARIATIONS IN GROWTH AND REPRODUCTION OF BAY SCALLOPS (*ARGOPECTEN IRRADIANS*) (LAMARK, 1819) FROM SIX SUBPOPULATIONS IN THE NORTHEASTERN GULF OF MEXICO

STEPHEN P. GEIGER,* JANESSA COBB AND WILLIAM S. ARNOLD

Florida Fish & Wildlife Research Institute, 100 8th Ave. SE, St. Petersburg, Florida 33701

ABSTRACT Bay scallops, *Argopecten irradians*, sustained a valuable commercial and recreational fishery in Florida during the middle part of the last century. In 1994, after decades of declining stocks, state managers closed this fishery to commercial harvest and severely limited the recreational harvest. In Florida, most bay scallops reproduce only once, generally during the fall at an age of roughly 12. The current 10-week recreational harvest season, July 1 through September 10, occurs at a time when somatic and reproductive tissues are changing rapidly in preparation for the fall spawning season. This study describes changes in tissue weights (reproductive, somatic, visceral) during the 2002 harvest season in scallops collected from six subpopulations along Florida's Gulf of Mexico coast. We observed tissue-specific patterns of weight change during the 7-month study and also noted regional differences. In three Panhandle sites (St. Joseph Bay, Lanark Village, and St. Marks), a shift from somatic growth to reproductive growth occurred later in the year and was more intense than in peninsular sites (Steinhatchee, Homosassa and Anclote). We also monitored recruitment of juvenile scallops at three of the sites from July of 2001 through June of 2003. There were protracted fall and winter peaks within a background of constant, low-level recruitment. The harvest limits allow each person to collect two gallons (7.55 L) of whole scallops or one pint (0.47 L) of adductor muscle meat each day. In June, just prior to the harvest season, the number of whole scallops that would be collected varied significantly between sites (range 55–203), as did the equivalent yield of adductor muscles (range 143–342). Muscle size peaked in August or September, depending on location. The allowable number of scallops collected within the volume-based limits had decreased (41–112 whole scallops or 84–116 shucked scallops) and between-site variability in the numerical harvest was lower.

KEY WORDS: *Argopecten irradians*, Florida, gonadal-somatic index, growth, harvest, recruitment, bay scallop

INTRODUCTION

Bay scallops, *Argopecten irradians* (Lamarck, 1819), were once a valuable commercial fisheries species for the state of Florida. During the 1950s, harvests commonly exceeded 100,000 pounds per year of adductor muscle (Murdock 1955) and peaked at 401,283 pounds in 1958 (Rosen 1959). There is also evidence for prehistoric sustenance harvest (Marelli & Arnold 2001) and a modern cultural heritage of recreational harvest. Stocks declined during the 1960s and 1970s, with a concomitant decrease in commercial harvest to levels between 10,000 and 20,000 pounds of adductor muscle per year by the 1980s (for example, see Joyce 1982). The abundance of scallops in many subpopulations declined to very low densities or disappeared completely. This decline was first documented in Pine Island Sound, then in Tampa Bay, the Anclote River Estuary and finally in the Homosassa River region. Similar declines have been observed in the western Florida Panhandle (Arnold et al. 2005).

In response to the decline of bay scallop abundance in Florida waters, harvest restrictions were instituted in 1985 and expanded in 1994. Management of the fishery targeted both commercial and recreational harvest. Commercial harvest was eliminated and recreational harvest was severely curtailed in 1994. All subpopulations south of the Suwannee River were closed to recreational harvest. The daily harvest limit of five gallons (18.88 L) of whole scallops per person was reduced to the current limit of two gallons (7.55 L) of whole scallops or one pint (0.47 L) of shucked adductor muscle per individual. The duration of the harvest season was reduced from 10 mo per year to 10 wk per year. Based on a survey program that was initiated in 1993, subpopulations are currently grouped into 3 classes: healthy (average density >25 scallops/600 m²), transitional (5–25 scallops/600 m²) or collapsed (<5 scallops/

600 m²). In 1994, all populations south of the Suwannee could be classified as either collapsed or transitional. To accompany the management actions, active restoration was initiated in 1998 and continues to this day. The goal of the restoration program was not to produce scallops for direct harvest but to create high-density spawning aggregations that may then seed the natural populations. Hatchery-reared scallops are held in cages at densities up to 300 per 0.6 m² in Crystal Bay, Homosassa River estuary, the Anclote River estuary (hereafter Homosassa and Anclote), Tampa Bay and Sarasota Bay. Subsequent increases in scallop abundance in the Homosassa subpopulation (Arnold et al. 2005) have been extensive enough that the recreational fishery was reopened in 2002.

In Florida, recreational harvest occurs during summer to accommodate the most popular means of collection, snorkeling. Current harvest of bay scallops in Florida is concentrated on a limited number of traditional subpopulations. Although the harvest season occurs immediately prior to the spawning season, previous research indicates that harvest occurs when muscle yield per individual is maximal (Barber & Blake 1983). A similar management approach is applied in the northeastern United States (bay scallop harvest is timed to maximize the yield of adductor muscle; Rhodes 1991, Estabrooks 2003). However, those animals are allowed to pass through their first spawning season and are harvested at a time when adductor muscles have begun a period of new growth, when most animals in the population are roughly 15 mo of age.

Bay scallops have been described as quasi-semelparous; most individuals spawn only once, but a small portion survive for one or more additional spawns (Orensanz et al. 1991). The traditional view of this species suggests that local subpopulations will spawn synchronously, either during warming spring or cooling fall periods (Sastry 1963, 1970). Recent research suggests that this is not always the case in Florida subpopulations. Arnold et al. (1998) monitored recruitment of spat in four distinct subpopulations on Florida's west coast from early August through late February. They found that whereas distinct peaks occurred in each locale,

*Corresponding author. E-mail: steve.geiger@myFWC.com

some recruitment occurred throughout the study in three of the four subpopulations. In a separate study, Bologna (1998) collected recruits in 12 of 28 mo during 1994 through 1996 in St. Joseph Bay, Florida. Over the course of the study, recruits were collected in 8 of the 12 calendar months. Secondary recruitment periods have also been observed in Long Island, New York (Tuttlebach et al. 1999).

Tissue growth in bay scallops is most rapid during the first year of life. Somatic growth will often precede gonadal growth, with energy stored in the adductor muscle as glycogen and protein and in the digestive gland as lipid (Barber & Blake 1981). Growth of these two organs may slow or be negative once gametogenesis begins, at which point gonad growth is very rapid (Bricelj et al. 1987, Barber & Blake 1983). Postspawn Florida scallops can suffer high mortality that is correlated with depleted energy reserves (Barber & Blake 1983). In northeastern United States populations, a higher percentage of scallops survive for additional spawns (Bricelj 1992). The scallops that survive a spawning cycle will initiate new growth in the adductor muscle, and gonadal-somatic indices do not attain as high a level during subsequent spawns, although actual gonad weight continues to increase (Bricelj 1992).

In this study, we explore small-scale variations in tissue-specific size and growth during a single harvest season (2002) in six subpopulations of bay scallops along Florida's Gulf of Mexico coast. The results from monitoring juvenile scallop recruitment are used to refine the interpretation of tissue growth and reproduction in three of those six subpopulations. The changes in the amount of allowable harvest, in terms of the number of scallops harvested, that accompany the changes in scallop shell and tissue (in particular adductor muscle) volume are described.

MATERIALS AND METHODS

Adult Collections

Argopecten irradians were collected from six sites along the Florida Gulf coast between Port St. Joe and Tampa Bay ($n = 1226$, Fig. 1). Four sites (Anclote, Homosassa, Steinhatchee and St. Marks) are part of the Big Bend region of Florida, a zero-energy coastline. The coastal seagrass bed found here varies between 11 and 35 km wide, an area approximately 3,000 km², and is dominated by *Thalassia testudinum*, *Syringodium filiforme* and *Halodule wrightii* (Iverson & Bittaker 1986). The St. Joseph Bay and Lanark sites are also low energy and have similar seagrass communities but are protected by barrier islands.

The bay scallop abundance at four of the six sites is routinely monitored (Arnold et al. 2005). Anclote was the southernmost site. During 11 y of survey there (1994–2004), the average scallop density varied between 0.15 and 47.35/600 m². During three of the years the density was considered healthy, during four years it was considered transitional, and during four years it was considered collapsed. It has not been open for harvest since 1993. Over the same period, the Homosassa population was considered healthy in 5 years, transitional in 3 years, and collapsed in 3 years. The study year, 2002, was the first year this site had been opened to harvest since 1993. Steinhatchee is the most stable subpopulation in the state; its density had been considered healthy in all years except 2004, when it was classified as transitional. The St. Marks and Lanark subpopulation densities are not monitored. The St. Joseph Bay subpopulation was also generally healthy (7 of the 11 y), although it was classified as transitional in 2 years and collapsed in 2 years. All four monitored subpopulations were considered to be healthy during 2002.

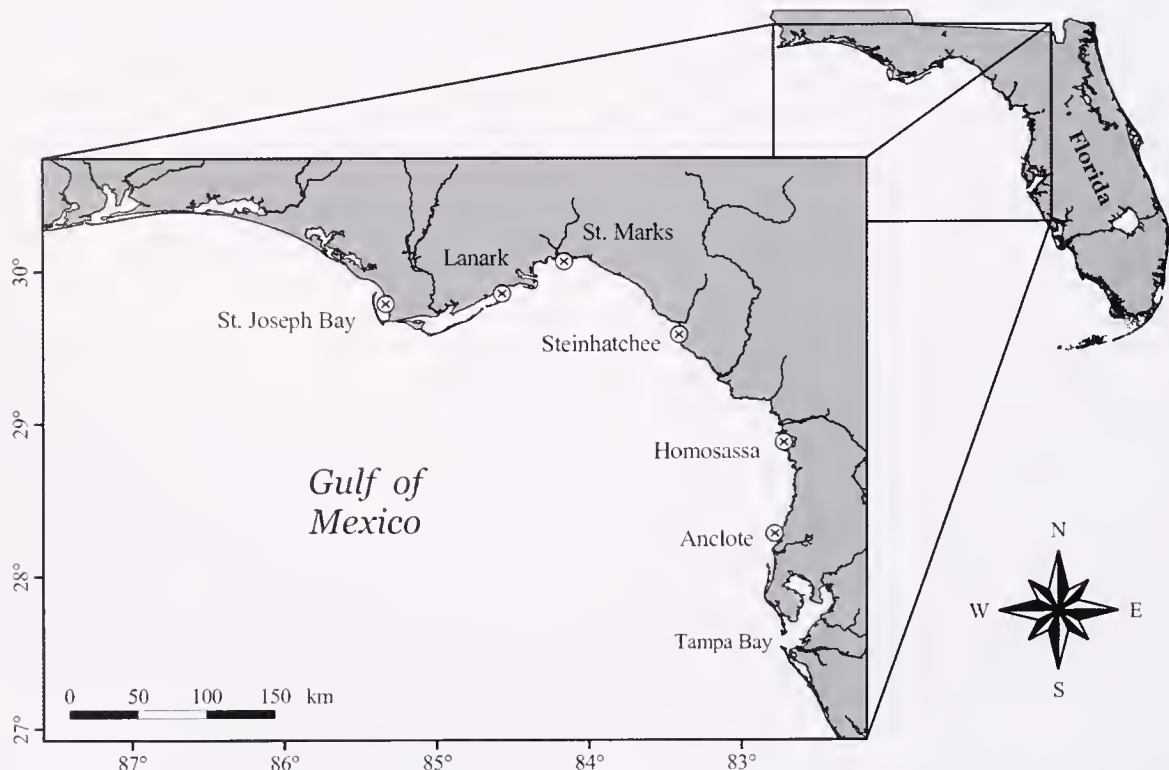

Figure 1. Locations of the six sampled subpopulations of Florida bay scallops, *Argopecten irradians*.

Our goal was to collect samples of 30 adults from each study site at 3-week intervals between May and September 2002 (Table 1), with at least one sample set collected before and one sample set collected after the harvest season. However, we began collecting samples as early as April 24 at Anclote and Homosassa and May 16 to May 17 at Steinhatchee, Lanark and St. Joseph Bay (because collections were made opportunistically). The study was terminated as early as September 3 at Steinhatchee (because of logistic constraints) and as late as October 10 at the Homosassa site (Table 1). Live scallops were collected opportunistically by hand and held in coolers for transport to shore. Samples collected at the Anclote and Homosassa sites were placed directly into freezers at the Fish & Wildlife Research Institute (FWRI) in St. Petersburg. Samples collected at all other locations were initially frozen and then were shipped overnight (packaged with dry ice) to St. Petersburg. All samples were then held at -80°C until analysis.

Shell and Tissue Analysis

Scallops were thawed for at least 1 hour before dissection. Many shells were covered in epibionts such as oysters, jingle shells and slippers snails. These fouling organisms were removed. The soft tissues of the scallop were separated into three components: gonad, adductor muscle, and all other tissue (hereafter termed viscera). Each of the tissues was placed into tared aluminum trays and the wet weights were measured to the nearest 0.1 mg. The volume of the adductor muscle was determined by submerging the muscle in a known volume of water in a graduated cylinder and observing the increase in volume to the nearest 0.2 mL. All components were then dried to constant weight in an oven at 60°C to 65°C for 20–24 h and the dry weights of each of the three tissues measured. Only mature specimens with a gonad dry weight <0.001 g were included in statistical comparisons.

After all tissue was removed, the valves of each scallop were rearticulated and the height, width and length were measured to the nearest 0.1 mm using digital calipers. To estimate the volume of a collection of whole scallops, rearticulated shells were taped back together and the entire sample from each sampling date and location was placed inside a 5,000-mL graduated beaker. The dry volume of the entire sample was estimated to the nearest 100 mL.

This process was repeated three times and an average volume was calculated to estimate the error variance associated with the packing of the shells.

The uneven sampling effort resulted in a matrix of sample dates and locations that was not amenable to a full factorial design. Initial analysis of the data was conducted using an analysis of covariance (ANCOVA), with the variable of interest as the dependent factor (shell height, adductor muscle dry weight, muscle volume, or gonadal-somatic index [GSI]), site as a categorical factor, and Julian date as a covariate. We calculated GSI as the ratio of reproductive tissue to all other tissue (muscle and viscera). When the ANCOVA model showed that the parameter of interest varied significantly either temporally or between sites, further analysis was conducted. We used either Dunn multiple comparison test or Tukey multiple comparison test for uneven sample sizes to identify differences between collection dates within each site or between sites within each month. We calculated growth rate for each sub-population by least squares linear regression, using shell height as the dependent variable and Julian calendar day as the independent variable. In each of the six regressions the residuals were normally distributed and homoscedastic. The slope of the resulting equation can be interpreted as the growth rate in mm per day.

Recruit Monitoring

As part of an ongoing study (Arnold et al. 1998, 2005) recruit collectors were deployed in 3 of our study sites: Anclote, Homosassa and St. Joseph Bay. Each recruit collector consisted of a 4-mm mesh, 1/2-bushel citrus bag containing a 30×48 -cm panel of 4-mm mesh polypropylene (Ambrose et al. 1992). The collector was attached 0.25 m above a cinder block anchor with 1/2-inch polypropylene rope. A small plastic donut float was attached to the opposite end of the trap, and a crab-trap float was attached to the distal end of the rope, each helping to keep the trap in a roughly vertical orientation off the bottom.

Each trap was placed in seagrass beds at depths of 0.5–1.5 m of water at low tide. Twenty-four collectors were deployed at each site, composed of 2 sets of 12, paired stations. At each station, one trap from each pair was pulled on alternate, 3-week target schedules, so that each trap soaked for roughly 6 weeks (median = 43

TABLE 1.

Summary of collection dates and sample size of bay scallops (*Argopecten irradians*) during 2002. The six collection locations are listed in the first column, and total sample sizes, *n*, for each location are shown in the last column. Individual collection dates and sample sizes for each date (given in parentheses) are listed by month.

Location	April	May	June	July	August	September	October	Total
Anclote	4/24 (28)	5/08 (19) 5/30 (29)		7/01 (29) 7/16 (30)	8/09 (33) 8/29 (30)	9/17 (30)	10/08 (32)	260
Homosassa	4/24 (30)	5/08 (34) 5/30 (30)	6/21 (23)	7/16 (30)	8/12 (30) 8/29 (30)	9/17 (30)	10/10 (30)	267
Steinhatchee		5/17 (29)	6/20 (30)	7/10 (30) 7/17 (30) 7/31 (30)	8/13 (30)	9/03 (30)		209
St. Marks			6/25 (33)	7/15 (30)	8/05 (30) 8/27 (33)	9/20 (30)		156
Lanark		5/16 (30)	6/05 (30)	7/09 (30) 7/31 (30)	8/22 (30)	9/12 (30)		180
St. Joseph Bay		5/17 (05) 5/26 (28) 5/31 (10)	6/12 (29)	7/17 (32)	8/15 (30)	9/19 (30)		154

days). Actual soak times varied between 36 and 84 days. Each trap was retrieved and placed in a labeled garbage bag without other preservation and was examined at a later date for scallop recruits. All surfaces (inside and outside of the citrus bag, and both sides of the polypropylene mesh) were examined with the naked eye, and all spat were removed and counted. Recruitment rate was calculated as the number of recruits divided by the number of days the trap had soaked. Mean recruitment rates were calculated weekly for each station by averaging the recruitment rate of all collectors at each location. Results are presented for traps retrieved during the period of July 2001 to June 2003.

RESULTS

Initial analyses using ANCOVA showed that each of the 4 variables of interest (shell height, adductor muscle dry weight, adductor muscle volume and the ratio of gonadal-somatic index) varied both between sites and temporally (Table 2). In each case the interaction term was also significant, indicating that the differences between the six sites were not consistent during the 6 months of the study. Further analyses were focused on elucidating where these differences existed.

The overall trend was for shell height to increase at each site during the course of the study but at rates that varied between sites. The growth rate ranged from 0.075 mm day⁻¹ at Lanark Village to 0.208 mm day⁻¹ at St. Marks (Table 3). Immediately prior to the July 1st opening of the recreational harvest season, mean shell heights at Anclote and Lanark were significantly larger than they were at the other four sites. During the middle of the harvest season (late July and early August) mean shell height had increased slightly and was uniform across the sample region, with the exception of one sample period (August 9–29), when the scallops at St. Joseph Bay were smaller than scallops at all other sites (Table 3). At the conclusion of the harvest season, shell heights at most sites had continued to increase slightly and were similar at most sites. The exceptions were the scallops at St. Marks, which had grown significantly larger than those at all other sites.

Adductor-muscle dry weight and volume both changed in similar ways during the course of the study, exhibiting two general trends. At St. Joseph Bay, adductor muscle volume increased throughout the season. At the other locations, muscle volume peaked in August then declined in September and October (Fig. 2). Adductor-muscle dry weight peaked in August and September at

TABLE 3.

Observed growth rates in bay scallops (*Argopecten irradians*). The growth rate (GR) of the shell height (mm day⁻¹) for each subpopulation, and coefficient of determination (r^2) for the least squares linear regression are given. Each regression equation was significant at $P \leq 0.001$. Sample sizes are the same as the total sample size in Table 1. Mean shell heights are given for the period immediately prior to harvest season (6/5 to 6/26; except Anclote, where samples were collected on the first day of the harvest season, 7/1), during mid-season (8/4 to 8/29), and after the harvest season had ended (9/12 to 9/20; except Steinhatchee, where the last collection occurred on 9/3, seven days prior to the end of the harvest season). Similar groups, as determined by Tukey multiple comparison test for unequal sample sizes, are indicated by the same letter.

	GR	r^2	Pre-season	Mid-season	Post-season
Anclote	0.090	0.4676	54.3 ^a	60.1 ^a	59.0 ^b
Homosassa	0.087	0.4897	45.8 ^b	57.3 ^a	58.9 ^b
Steinhatchee	0.132	0.5023	43.8 ^b	57.7 ^a	55.9 ^b
St. Marks	0.207	0.5663	43.1 ^b	56.2 ^a	63.3 ^a
Lanark Village	0.075	0.4056	54.1 ^a	59.6 ^a	60.7 ^b
St. Joseph Bay	0.135	0.6301	45.7 ^b	54.5 ^b	57.8 ^b

St. Marks and St. Joseph Bay. At the other four sample locations, August peaks were followed by declines in September and October (Fig. 3).

Gonad dry weight also changed over the course of the study, again having two general trends. At the peninsular locations (Anclote, Homosassa and Steinhatchee) gonad dry-weight initially increased slowly then leveled off in August and September. In Panhandle sites (St. Marks, Lanark and St. Joseph Bay), gonad dry weight also initially increased slowly but then increased rapidly in September to a much greater extent than at the three peninsular sites (Fig. 4).

Changes in gonadal-somatic index (GSI) followed two distinct trends. GSI at all sites was low when the study was initiated; mean values ranged from 0.02–0.05 during April through June (Fig. 5). At the three peninsular sites, significant increases in GSI were observed in August and September, but the mean GSI never exceeded 0.12. At the three Panhandle sites, the increases in GSI that

TABLE 2.

Analysis of covariance results from analyses of site-specific and temporal variation in four measures of growth and reproduction in bay scallops (*Argopecten irradians*) during 2002: shell height, adductor muscle dry weight, muscle volume, and the ratio of reproductive to somatic tissue. For each variable, there was one degree of freedom for each of the model and date components, five degrees of freedom for both the by-site comparisons and interaction terms, and 1,214 degrees of freedom for the error term. The mean square and F value for ANCOVA results for each regression term are given. All P values were <0.01 .

		Error	Intercept	Site	Date	Site × Date Interaction
Shell height	MS	23.26	25177.70	539.65	25779.99	538.68
	F		1082.60	23.20	1108.49	23.16
Adductor dry weight	MS	0.12	30.39	1.03	30.71	1.03
	F		250.78	8.47	253.49	8.51
Muscle volume	MS	1.34	531.23	14.00	536.62	14.06

Gonad:muscle ratio	MS	0.0011	1.0101	0.0989	1.0147	0.0990
	F		892.88	87.41	897.01	87.50

Figure 2. Mean volume of adductor muscles of bay scallops, *Argopecten irradians*, from six subpopulations along Florida's Gulf of Mexico coast. Midpoint, mean; box, standard error; bars, standard deviation. Groups that are not significantly different are indicated by the same letter(s).

occurred in September were more pronounced. Mean GSI in September increased to values of 0.20 in St. Marks, 0.14 in Lanark and 0.19 in St. Joseph Bay.

Three trends in the number of scallops estimated to be harvested by someone collecting their recreational limit were observed. First, the number of scallops that can be legally harvested generally declines as the season progresses, regardless of which measure is used (Fig. 6). This trend was not entirely linear, and an increase in the number of scallops harvested using the one-pint limit did occur late in the season because muscle size began to decline. Second, more scallops could be legally harvested by someone shucking their scallops at sea and collecting one pint of meat than by someone collecting two gallons of whole scallops and shucking them on shore. This pattern is especially true early in the season, but the disparity declines as the season progresses. Finally, during the harvest season Lanark had the largest scallops with the largest adductor muscles, so a fisher harvesting their legal limit from this area would take fewer scallops than at any other area.

If the harvest season were to open in May, a legal harvest would range from 65–215 whole scallops and between 213 and 429 shucked scallops (Fig. 6). Under current regulations, when the season opens on July 1, legal harvest would range from 55–203 whole scallops or 143–342 shucked scallops. When scallops at most sites achieved peak muscle size during early August (midway through the harvest season), legal harvests ranged from 41–112 whole scallops or 84–116 shucked scallops. Thus, there is a dis-

parity between sites in the number of scallops that could be legally harvested, but this disparity declines as the season progresses.

In each year, all three monitored subpopulations had recruitment that occurred with peaks but also with protracted periods of very low levels of recruitment (Fig. 7). At Anclote, spat settled over a protracted period in both years. Recruitment peaked from late October 2001 through January 2002, but some recruits were collected in every sample period from August 2001 through May 2002. Modest peaks also occurred in August and during October through December 2002. At the Homosassa site, spat recruited to collectors from August through June, with peaks in September 2001 through January 2002 and again in August through November of 2002. In St. Joseph Bay, we observed recruitment throughout the study. A large peak in recruitment began in October 2001 and continued through January 2002. A more modest peak in recruitment was observed in late October and continuing through November in 2002. One clear trend is that Homosassa traps (maximum rate of 0.38 spat per bag per day) collected scallops at a rate roughly one order of magnitude less than Anclote traps did (maximum rate of 6.3 spat per bag per day), and Anclote traps collected scallops at a rate roughly one order of magnitude less than traps in St. Joseph Bay did (maximum rate of 48 per bag per day).

DISCUSSION

In the six subpopulations of bay scallops that we sampled from Florida waters, we observed higher than expected variability be-

Figure 3. Mean dry weight of adductor muscles of bay scallops, *Argopecten irradians*, from six subpopulations along Florida's Gulf of Mexico coast. Midpoint, mean; box, standard error; bars, standard deviation. Groups that are not significantly different are indicated by the same letter(s).

tween sites and predictable but still variable temporal changes. In each subpopulation, we documented growth and development towards a maximal spawning condition in early fall, as predicted by previous studies (Barber & Blake 1983). All six subpopulations showed a positive trend in shell height and gonad weight, and all of the subpopulations experienced a relative increase in mean muscle weight and volume during the initial portion of the study. However, there were regional differences in the amount of energy devoted to somatic growth versus gonad growth and reproduction. The scallops from the Florida Panhandle sites had more pronounced increases in gonadal-somatic index in September than did scallops from the peninsular sites.

Changes in the value of a ratio can occur when either of its components change but can also remain the same when both components change similarly. In this study, increases in GSI might be expected at the peninsular sites, because scallops at all three had decreases in muscle weight and volume in the fall. However, gonad weight also declined (indicative of a spawning event), so the ratio changed little. These observations do not support the expectation that energy reserves were transferred from muscle to gonad. In two of the three Panhandle sites (Lanark and St. Marks), scallop muscle weight declined, whereas gonad weight increased, resulting in significant increases in GSI, evidence that would support the expectation of a transfer of energy from muscle to gonad. These two subpopulations are most similar to scallops observed by Sastry (1966) and Barber and Blake (1985) in which energy reserves in muscle and digestive gland were transferred into reproductive tissue.

In St. Joseph Bay, both muscle and gonad weights increased, whereas GSI increased greatly. Thus, a contrast between scallops in the two regions suggests that in 2002, those at peninsular sites had limited energy available for an early fall spawn, whereas those at Panhandle sites had relatively more energy for a late fall spawn, as seems to be evidenced by the actual size of the gonad or the GSI.

Studies of recruitment can supply evidence supporting the assumption that peaks in gonad weight and GSI are correlated with a successful spawning event. Settlement of scallops on spat collectors occurred contemporaneously with peaks in GSI (this study). At Anclote, spat settled over a protracted period (August 2002 through January 2003). The initiation of this recruitment was concurrent with the weak peak in GSI. Similarly, at the Homosassa site, a weak peak in GSI was observed in August, and again, spat recruited to collectors in August through December. In St. Joseph Bay, before we discontinued this study, we observed a peak in GSI in September. A large peak in recruitment began in November 2002 and continued through January of 2003, suggesting that the large energetic reserves we observed translated into a large recruitment event in St. Joseph Bay.

Bologna (1998) suggested that the St. Joseph Bay subpopulation spawned year-round but that the peak of the spawning season varied from year to year. In that study, gonadal-somatic condition peaked during the winter, but recruits were collected in nearly every month. Barber & Blake (1981, 1983) found that the scallops in the Anclote estuary devoted most of their assimilated energy to somatic growth in spring. Histological analysis indicated that oo-

Figure 4. Mean dry weight of gonads of bay scallops, *Argopecten irradians*, from six subpopulations along Florida's Gulf of Mexico coast. Midpoint, mean; box, standard error; bars, standard deviation. Groups that are not significantly different are indicated by the same letter(s).

genesis was occurring without large increases in gonad size during May. Muscle, mantle and digestive tissue weights peaked in August. Further tissue growth was limited to increased gonad size in the early fall, including transfers of stored energy from muscle and viscera to the gonad. Cytoplasmic growth and vitellogenesis were associated with both increases in gonad weight (or body component index) and plateaus then declines in muscle weight (Barber & Blake 1983). The 3-year study found that the initiation of this process varied between the beginning of June and the middle of July but always peaked in September. Their observations compare well with ours.

The variability observed in shell size showed no easily discernable regional pattern. The two sites at which shell sizes were statistically larger than the others at the beginning of the study (Lanark and Anclote) are interspersed spatially among the other four sites. By September, all mean shell heights were around 60 mm at all of the sites. The simplest explanation would be that at or near that size, scallops along Florida's gulf coast begin to use available energy for reproduction. Evidence from recruitment studies supports this claim. At the Anclote and Homosassa sites, recruitment began in August and continued through the fall, whereas very little recruitment was observed in St. Joseph Bay (whose mean shell height was smallest in 2002) until January 2003. Alternatively, St. Joseph Bay animals may have been devoting energy to spawning in the spring of 2002, as suggested by observed recruitment throughout the spring, whereas the Anclote and Homosassa subpopulations did not produce a large number of spring

recruits. The St. Joseph Bay animals may have been in a refractory state during summer of 2002 in preparation for a second major spawning event.

One possible explanation for the discrepancies in sizes between sites is that the subpopulations with smaller mean sizes in May had recruited more recently. The adults used in this study would have recruited sometime during fall 2001 or winter 2002. Evidence from recruitment in fall of 2001 and winter and spring of 2002 does not support the hypothesis for earlier recruitment at Anclote and Homosassa relative to St. Joseph Bay. At the Homosassa site, minor peaks in recruitment occurred in September through October and in December, but some recruits were collected in all months from August 2001 through May 2002. Both the St. Joseph Bay and Anclote subpopulations recruited in fairly distinct peaks during late fall 2001 and early winter 2002, but if anything, the peak recruitment in St. Joseph Bay was earlier, around November 1st, than at Anclote, which peaked closer to December 1st. The overlapping recruitment periods indicate that differences in settlement date were not responsible for the differences in size during May of 2002.

A second possible explanation for the difference in size between subpopulations is that those differences are genetically based. Marelli et al. (1997) and Marelli & Arnold (2001) studied morphological and genetic differences between Florida's Gulf of Mexico bay scallop subpopulations. They suggested that the morphological differences between local subpopulations were minimal and that all of the subpopulations studied were part of the local

Figure 5. Mean gonadal-somatic indices of bay scallops, *Argopecten irradians*, from six subpopulations along Florida's Gulf of Mexico coast. Midpoint, mean; box, standard error; bars, standard deviation. Groups that are not significantly different are indicated by the same letter(s).

subspecies. In those studies, neighboring subpopulations were often more dissimilar than more distant populations and little or no geographic pattern was apparent within the Florida subpopulations. We conducted size-adjusted principal components analysis on morphological data following Marelli et al. (1997) and found results similar to theirs (unpublished data). There was no readily apparent difference in the shape of any of the scallop subpopulations' shells nor was there a discernable geographic trend (two of the closest subpopulations, St. Marks and Lanark, were the most different). Patterns of gene flow between subpopulations, as influenced by the complex nearshore hydrography of the Florida Shelf (Yang & Weisberg 1999), may affect spatial and temporal patterns of genetic variation. It seems unlikely that any of the differences observed in tissue weights can be explained by genetic variation; rather, small-scale variation in the physical or biotic environments probably resulted in the observed differences in 2002.

Bricelj et al. (1987) summarized the changes in spawning patterns of bay scallops from 3 latitudinally distinct populations: Massachusetts, New York and Florida. The general conclusions were that northern populations showed more discrete peaks in spawning activity, whereas southern populations had more protracted spawning seasons. In the northern populations, periods of somatic growth occurred in spring, prior to spawning, and again in summer and early fall. In the northern populations, a considerable portion of the population will store sufficient energy reserves to overwinter and spawn a second time. These animals will rapidly resume growth of their adductor muscles during the fall. In the current study, we

observed two distinct patterns of growth. In the peninsular subpopulations, changes in muscle and viscera accounted for most of the early-summer growth. Spawning began in late summer, reminiscent of the pattern previously observed in scallops from Massachusetts (Sastry 1970), albeit more protracted in Florida's scallops. Scallops from Florida's Panhandle subpopulations continued to grow until at least the conclusion of our study, and reproduction likely peaked late in the fall, reminiscent of the spawning patterns of populations from the Anclote estuary (Blake & Barber 1983) or North Carolina (Sastry 1970).

The recreational harvest season in Florida begins during a period when scallops are undergoing rapid growth, but the initiation of this period of rapid growth varies between sites. Thus, at the beginning of the season, there is high between-site variability in shell size and adductor muscle mass. The growth is most notable in changes in soft tissues, adductor muscles and gonads. As a result, at some locations, many more scallops could legally be harvested than at others. This finding is especially true if the scallops are shucked at sea. Between July 1st and August 1st, the number of legally harvested shucked scallops declines by about one third because of increases in adductor muscle volume, a process observed at all sites. This decline is less pronounced for whole scallops.

A short delay in the harvest season would result in fewer scallops being taken for harvest, possibly allowing more scallops to survive until fall spawning. A delay in the harvest season would also allow a more simple understanding of harvest, because most

Figure 6. Estimates of recreational harvest limits for bay scallops, *Argopecten irradians*. Open boxes, two gallons whole scallops; shaded bars, 1-pint adductor meats. The collection sites are abbreviated as follows: Anclote, AN; Homosassa, HO; Steinhatchee, ST; St. Marks, SM; Lanark, LA; St. Joseph Bay, SJ.

areas would have a similar number of scallops being harvested by each person collecting their limit. However, natural mortality rates are poorly understood in Florida's scallop subpopulations, and a delayed harvest may not result in a large net gain in the size of the reproductive population. Estimates of instantaneous daily natural mortality in Florida between 0.01 (Greenawalt 2002) and 0.014 (Bologna 1998) indicate that there would be roughly 25% fewer

scallops present on opening day if it were moved from July 1st to August 1st. The effect of delaying the fishing season would then depend on whether fishers continued to collect scallops at the same rate 1 month later (potentially very deleterious) or if fishing mortality, as a percentage of the population, remained steady (little net difference).

Another consideration in changes of the harvest season is that

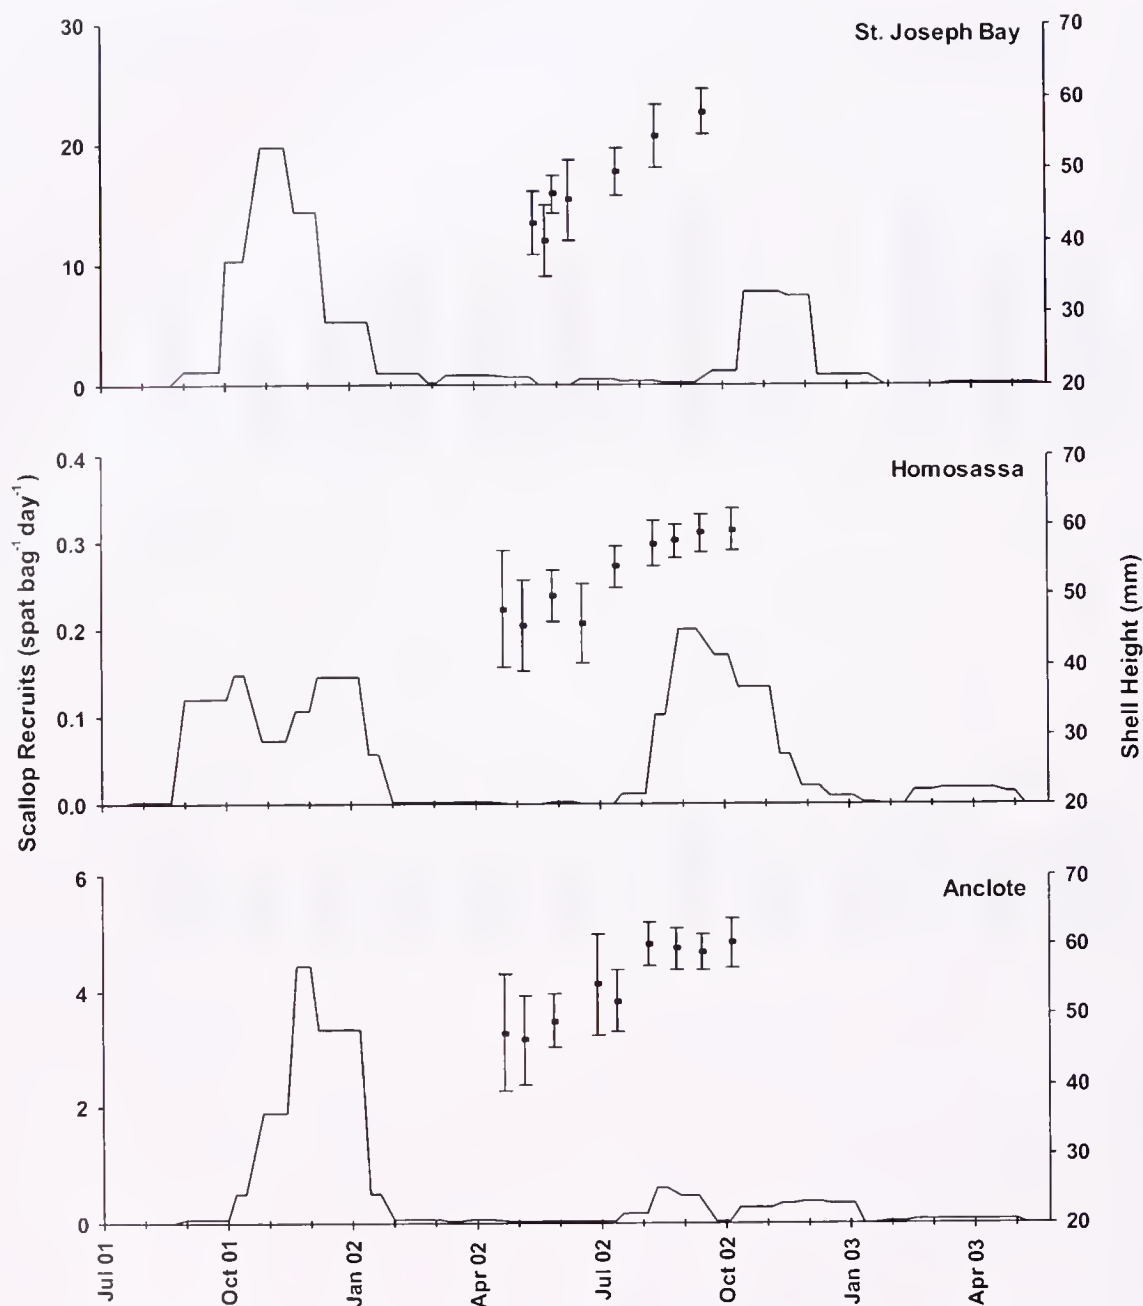

Figure 7. Recruitment rates and adult shell heights (mean \pm SD) of scallops from three Florida subpopulations of bay scallops, *Argopecten irradians*.

Florida's scallops begin to lose muscle mass in September, as energy is transferred to the gonad (this study; Barber & Blake, 1985). A delay in opening the harvest season, assuming the 10-wk duration was maintained, might actually cause an increased harvest of those scallops that had managed to survive until the fall spawning season. Smaller adductor meats would lead to increased harvest if a person collected the one-pint limit of meat, but the larger shells present in the fall would result in smaller yield for a person collecting a limit of two gallons of whole scallops. A reduction in the duration of the harvest season would probably be unappealing to the tourism industry and recreational fishers unless considerable gains in stability of the population were realized. An analysis of the tradeoffs between biological gain and potential economic

losses resulting from changing the dates of the harvest season should be made before any management actions are proposed.

ACKNOWLEDGMENTS

This study would not have been possible without the assistance of the many people who provided samples: Melanie Parker, Sarah Peters, Jaime Greenawalt, Troy Tuckey, Dan Marelli, Tammy Summers and Robert Turpin. April Granholm, Kim Parthemore, and Chris Matterson provided assistance in the laboratory. Sarah Walters, Heather Wolfe, Jim Quinn, Judy Leiby and two anonymous reviewers provided valuable comments on earlier drafts of this document. This research was supported by revenues collected under the Florida Saltwater Fishing License.

REPRODUCTION AND SPAWNING IN CALICO SCALLOPS, *ARGOPECTEN GIBBUS*, FROM BERMUDA

SAMIA SARKIS,¹* CYR COUTURIER² AND ANDREW COGSWELL³

¹Department of Conservation Services, P.O. Box FL 588, Flatts FLBX, Bermuda; ²Marine Institute, Box 4920, St. John's, NL, Canada, A1C 5R3; ³Bermuda Biological Station for Research, Ferry Reach GEO1, Bermuda

ABSTRACT The gametogenic cycle and breeding season of the calico scallop, *Argopecten gibbus* was examined in Bermuda using quantitative and qualitative methods. Gonadal index varied seasonally, a rapid increase occurring in the winter months from January to March, and reaching maximum values in March and April. Greatest gonad growth and spawning were associated with low seawater temperature and low food levels. Variations in muscle indices implied a partial reliance on muscle reserves during the early stages of oogenesis. The later stages of ovarian growth (vitellogenesis and oocyte maturation) seemed to show a direct dependence on food supply. Histological analysis indicated the initiation of gamete development in early fall, when cell differentiation was first observed; oocyte ripening took place in late fall and early winter, reflected in increased oocyte diameters and gonadal indices. The lack of spawning activity during the hot summer months was seen histologically by the high proportion of spent cells in the gonads and a reduction in oocyte size, resulting in a minimal gonadal index. Individuals with gonad indices above 2 and mean oocyte diameters exceeding 50 μ m were induced to spawn with thermal shocks, exceeding 70% response rate in oocyte release in all trials. The present study extends our limited knowledge of the reproductive cycle in this subtropical scallop while providing a useful index to evaluate spawning readiness in cultured broodstock for routine hatchery purposes.

KEY WORDS: gametogenesis, scallops, spawning, reproduction, subtropical, *Argopecten gibbus*

INTRODUCTION

Calico scallops, *Argopecten gibbus*, are largely restricted to the subtemperate and tropical waters of western North Atlantic with the major stocks distributed from Cape Hatteras, North Carolina to the northeastern Gulf of Mexico (Waller 1969); calico scallops have also been collected from the Greater Antilles, Bermuda and the western portions of the Gulf of Mexico (Waller 1969). This species supports a commercial fishery off the East Coast of the United States (Blake & Moyer 1991), and its large-scale culture has been investigated in Bermuda for the purpose of stock enhancement and commercial activity since 1996 (Sarkis et al. 2003). Although much has been reported in the literature for the related bay scallop species, *Argopecten irradians*, little information is available for the calico scallop, especially for those inhabiting Bermuda waters. Data available from the commercial fishery in the United States has generated information on settlement, abundance and yield based on field studies (Roe et al. 1971), population assessments (Cummins 1971) and spawning periods in relation to environmental parameters (Allen 1979, Miller et al. 1981).

Knowledge of the reproductive cycle is necessary for restocking and/or mariculture purposes. Moyer and Blake (1986) have assessed the reproductive cycle of calico scallops in Florida using gonadal indices. However, as documented in *Argopecten irradians*, latitudinal differences occur in the timing of gametogenesis and reproduction; in general, reproductive events occur later in the year and at higher water temperatures in more southern latitudes (Barber & Blake 1991).

The present study describes the gametogenic cycle of *Argopecten gibbus* inhabiting Bermuda waters. Although the use of gonadal indices is a simple, fast and inexpensive method, which may be routinely used in hatcheries, verification of reproductive events pertaining to gamete development is obtained by histological techniques (Couturier & Newkirk 1991). In the present study,

quantitative (gonad index) and qualitative (histology) methods were used to assess the reproductive status of calico scallops. This further allowed for testing the validity of relying on gonadal indices for controlled spawning induction of *A. gibbus* in the hatchery.

MATERIALS AND METHODS

Calico scallops reared in suspended cultures in Harrington Sound, Bermuda (32°N, 64°W) were collected on a monthly basis from December 2000 to December 2002. Each sample consisting of 30 scallops >50 mm in shell height was transported in water to the pilot hatchery at the Bermuda Biological Station for Research (BBSR) and maintained in an open filtered seawater system for a 24-h period, allowing for gut clearance. Scallops were scrubbed of epibiota and shell height and length measured to the nearest 0.1 mm, with vernier calipers. Scallops were blotted dry and total wet weight was determined using a Sartorius balance (to nearest 0.01 g).

A subsample of 15 scallops was used for determination of gonad and muscle indices on a monthly basis for a two-year period from December 2000 to December 2002; in the second year of sampling, December 2001 to December 2002, a second monthly subsample of 10 scallops was taken simultaneously for histological analyses.

Tissue Indices

Various condition indices have been used to characterize the apparent "health" of bivalves. Lucas & Beninger (1985) in a critical review of several of these indices, concluded that the dry tissue weight:dry shell weight ratio gave meaningful information about the physiological state of the animal, including reproductive activity. In the present study, gonad and muscle indices were calculated separately; the former reflecting gonad development, and the latter as an indication of seasonal metabolic changes, possibly associated with gametogenesis (Sarkis 1993). Gonads and adductor muscles were dissected, and dried to constant weight in an oven at 80°C. Tissue indices were calculated as follows: (Dry weight of

*Corresponding author. E-mail: scsarkis@gov.bm

tissue/dry empty shell weight) $\times 100$; where a high gonadal index is indicative of mature gonads, and a lower index reflects the onset of gametogenesis or spent gonads.

Histology

To obtain further insight into oogenesis and oocyte maturation, samples of gonads were dissected monthly and prepared for histological analysis. A small distal portion of the gonad (5 mm \times 5 mm) was fixed in Bouin's fluid for 48–72 h and stored in 70% ethanol until sectioning (Naidu 1970). Fixed ovarian tissue samples were processed for histology according to standard methods for marine bivalves (Howard et al. 2004). The fixed tissues were dehydrated through an ascending alcohol series, embedded in wax, cut to 5- μ m sections and stained with hematoxylin and eosin.

Thin sections were examined under a compound microscope ($\times 100$ magnification) for developmental purposes and categorized into 6 stages based on Naidu (1970) and Couturier and Newkirk (1991) as follows—Stage 1: undifferentiated, follicular structure is indistinct, and no sex cell primordia; Stage 2: differentiated, oocyte development commences, primary oogonia are visible, sex cells range from 15–25 μ m in diameter; Stage 3: developing, mostly previtellogenic and vitellogenic oocytes, follicle lumen is open or only partially occluded, and oocyte diameter ranges from 30–70 μ m; Stage 4: ripe, gonads show packed follicles, the follicular lumen is occluded, there is no interfollicular space visible, and oocytes range 60–70 μ m in diameter; Stage 5: spawning, the follicle lumen is opening, follicle size diminishing and ripe oocytes range 60–70 μ m; Stage 6: spent, follicles are empty and frequently filled with hemocyte aggregations on slide preparations, and an occasional atretic oocyte is present.

Each scallop was categorized according to one of the previous gonad development stages, and the frequency (%) of each stage determined for monthly samples. The data were plotted as cumulative histograms while assessing the developmental stage of each scallop under the microscope, the diameters of 10 oocytes were measured randomly in each individual using an ocular micrometer. Photomicrographs of representative developmental stages were obtained under $\times 100$ magnification using a digital photomicroscopy setup (see Fig. 3 later).

Spawning Induction

Results from spawning induction, performed during the course of four years of hatchery operation (1996–1998, 2002), are presented here for comparison with conclusions drawn from in-depth histological data determined within the scope of this study. Cultured adults were obtained from field sites during winter/early spring (December to April), and the gonadal index calculated as previously described on a subsample. Spawning induction was attempted on 30 scallops by standard thermal cycling shocks (Sarkis et al. 2003, Bourne et al. 1989). The proportion of spawning females was calculated for each trial, as an indication of spawning success. Comparisons were made between the percentage response and histological state.

RESULTS

Tissue Indices

Gonadal and muscle indices for the calico scallop reared in Bermuda waters are shown in Figures 1 and 2, respectively. Al-

Figure 1. Seasonal gonadal index of cultured *Argopecten gibbus*. Data points represent mean \pm SD ($n = 15$).

though fluctuations in gonadal indices were large, especially in the first year of sampling, the trend was for maximum values of the index during the winter months, and minimum values during the summer months. There was a slight increase in gonadal indices during the autumn months (September to December), remaining relatively low until December (0.2–0.9). Thereafter, a rapid increase in gonad weight occurred in the winter months, from January to March, reaching maximal values in March and April.

The time required for scallops to attain maximum gonad index varied slightly from year to year, with maximum values observed in April in 2001 (3.07 ± 1.18), and in March during 2002 (2.13 ± 0.83). Variation in gonad condition among individual scallops was large particularly throughout the spawning season from February to May, implying perhaps low synchronicity in spawning among conspecifics. Gonadal indices were at their lowest during the summer months from June to August, ranging from 0.12 (± 0.38) to 0.17 (± 0.12) in 2001, and 0.33 (± 0.14) to 0.41 (± 0.12) in 2002, representing a "rest" period.

The trend in adductor muscle indices was not as distinct as that seen for gonadal indices and seasonal fluctuations were not as wide, although they were apparent (Fig. 2). Maximum values were generally recorded at the end of the summer months in September,

Figure 2. Seasonal variation in adductor muscle index in cultured *Argopecten gibbus*. Data points represent the mean \pm SD ($n = 15$).

reaching 5.33 ± 0.65 in 2001 and 4.99 ± 0.92 in 2002. These coincided with low gonadal indices (compare Figs. 1 and 2). Muscle indices decreased throughout the autumn, as gonadal indices started to increase. As gonadal indices peaked from January to April, muscle indices remained low, fluctuating between 3.01 ± 0.47 and 4.06 ± 1.03 in both years of the study. Variations among individuals were seen on a monthly basis, as for gonadal indices.

In summary, gonadal indices indicated large seasonal fluctuations with the occurrence of well-defined peaks of gonadal activity during the winter months (January to April), and a period of inactivity during the summer months. Muscle indices showed, to a certain extent, inverse seasonal fluctuations to those recorded for gonadal indices.

Histology

Photomicrographs of ovarian developmental stages are shown in Figure 3. Each stage is easily identified by the type of cells

present or absent, the shape of the follicles containing gametes, and the size of the oocytes.

The first appearance of cell differentiation was observed in September, when the gonad consisted of 60% developing cells (Fig. 4). The first appearance of ripe oocytes was recorded in December, and the gonad at this time consisted mainly of developing and ripe cells (90% in 2001 and 100% in 2002) (Fig. 4). Oocyte ripening occurred during the winter months, from December to March, as the proportion of ripe cells increased to 80%, 90% and 70% of the gonad in February, March and April, respectively (Fig. 4). During these three months, the gonad samples consisted of 100% ripe and spawning individuals, implying a readiness to spawn. Between April and June, the proportion of spawning and spent individuals increased, indicating the end of spawning activity (Fig. 4). By the month of August, 100% of the scallops seen were spent and contained no gametes (Fig. 4).

Seasonal variations in mean oocyte diameter are recorded in

Figure 3. Stages of ovarian development in cultured *Argopecten gibbus* ($\times 100$ magnification). A, undifferentiated; B, differentiated; C, developing; D, ripe; E, spawning; F, spent.

Figure 4. Qualitative assessment of reproductive patterns in the ovarian portion of the gonad of cultured *Argopecten gibbus* from Bermuda. $n = 10$ animals per sample date.

Figure 5. Microscopic observation of histological sections of ovaries revealed that oocyte size was comparable in individuals collected during oocyte ripening in the winter, from December to April, ranging from $53.7 \mu\text{m}$ to $63.5 \mu\text{m}$. The dramatic decrease in oocyte size to $23.1 \mu\text{m}$ seen from April to June coincided with the histological evidence of spawning and the lack of gametogenic activity seen during the hot summer months.

Spawning Induction

Results obtained in the hatchery from spawning induction trials yielded a spawning success of 70% to 90% of the females induced (Fig. 6) when gonadal indices exceeded 2. Such individuals generally responded to the thermal treatment and released gametes within 90 min of stimulation and most individuals did so in a synchronous manner. Attempts to spawn individuals with gonadal indices below or equal to 2 resulted in variable success with generally fewer than 40% of individuals responding to the thermal shock (Fig. 6).

DISCUSSION

The present study suggests that calico scallops in Bermuda undergo reproduction mainly from December to April, and possi-

Figure 5. Seasonal variation in mean oocyte diameter in culture *Argopecten gibbus*. Points represent the mean + S.D. ($n = 100$).

Figure 6. Relationship between gonadal indices (line, mean + SD, $n = 15$) and female spawning response (bars, %, $n = 30$ on each attempt) following thermal stimulation of calico scallops in the hatchery.

bly May. Gamete differentiation and development began in September, associated with a mean oocyte size of $<20 \mu\text{m}$, low gonadal indices and maximal muscle indices. Oocyte development occurred throughout the fall, coinciding with a gradual increase in mean oocyte diameter and gonad weight, and a reduction in adductor muscle indices. The first ripe scallops appeared in December when mean oocyte diameter exceeded $50 \mu\text{m}$ and gonadal index approached 1. Oocyte ripening continued during the winter months, associated with low muscle indices and a rapid increase in gonad weight yielding by February a gonadal index close to or above 2 with 80% of the scallops classified as ripe and showing some evidence of spawning in histological sections. The spawning period extended into March and April, and was reflected in the responses obtained from controlled spawning trials at the BBSR hatchery, where induced individuals released gametes between February and April. Optimal spawning responses were obtained when gonadal index was above 2, coinciding with histological analyses showing ovaries with high percentage of ripe oocytes ($>70\%$). After the spawning period, both gonadal index and oocyte diameters declined rapidly in late spring/early summer, and histology showed increased proportions of spent individuals. By August, gonads consisted of spent cells only, resulting in minimal gonadal indices and coinciding with a lack of spawning activity during the summer months.

The spawning period of the calico scallop in Bermuda, extending over the winter months, is associated with colder water temperatures and lower food availability. This cycle differs from that recorded for the same species in Florida (Moyer & Blake 1986), where two spawning periods are observed, the first in late spring (April to June), and the second in the autumn. As mentioned previously, latitudinal differences in gametogenesis have been recorded within a species, explained in part by spatial differences in environmental influences, namely those of food and temperature (Barber & Blake 1985, MacDonald & Thompson 1988).

Temperature is most often cited as influencing bivalve reproduction and triggering spawning. Gamete maturation for *Argopecten gibbus* in Bermuda coincided with minimal sea surface temperatures ranging from 16°C to 18°C (Doug Connelly, unpublished data). Blake & Moyer (1991) found that the required threshold temperature for gonad development and ripening for the same species in Florida was of 19°C to 20°C . They further concluded that temperatures above 22°C stopped gonad ripening and spawning did not occur, which agrees with the results in the present study where spawning terminated in late spring at temperatures above

21°C, and a lack of gametogenic activity was seen during the warmer months (July and August), when sea surface temperatures reached a maximum (29°C) (Doug Connelly, unpublished). However, in keeping with the annual variations in gonadal indices reported in the present study, Manuel (2001) recorded yearly fluctuations in peak spat settlement periods in the field. These variations may be associated with changes in sea surface temperatures and food supply between years, because environmental characteristics of Bermuda's inshore waters, habitat to these scallop species, have been known to be wind-driven and hence highly variable; this is especially apparent in the timing of "bloom" conditions, expressed as chlorophyll *a* (1.93 µg chl *a*·L⁻¹), occurring during late fall or early winter (November and December) (Doug Connelly, unpublished). The trend seen in the muscle index points to the relationship between "bloom" occurrences and gonadal development in the early stages of oogenesis, and it implies to a certain extent a direct dependence on external food supply for oocyte ripening during periods of low food availability in late winter/early spring (0.42 µg chl *a*·L⁻¹) (Doug Connelly, unpublished). Similar conclusions were drawn by Manuel (2001) for another scallop species inhabiting Bermuda waters, *Euvola (Pecten) ziczac*.

Thermostimulation has proven efficient and rapid for inducing spawning in calico scallops in Bermuda with a mean gonadal index above 2, compared with other species (Monsalvo-Spencer et al. 1997). To date, thermal shock seems to be the most efficient method, for inducing sperm and ova release in hatchery scallops (Monsalvo-Spencer et al. 1997), and this is especially true for pectinidae, where a critical temperature range or minimum threshold temperature has been most frequently implicated in the initiation of spawning (Barber & Blake 1983, Moyer & Blake 1986).

However, variable responses have been obtained using thermal shock induction in Bermuda with scallops having a gonadal index close to or below 2. This points to the influence of other factors in controlled spawning events, perhaps related to hatchery procedures and/or to natural spawning cues. For example, it has been shown that spawning in cultured and natural populations of various scallops does not appear to occur until the majority of the animals in a population have ripe gonads, normally above 70% or more of the populations (Lubet et al. 1991, Couturier 1994, Lohrmann & Von Brand 2005). In this study, fluctuations seen in gonadal index among individuals on a monthly basis indicate a heterogeneity within the sample, and should be given closer consideration when mean index is low; it may well be that sample size for hatchery spawning induction needs to be increased at this time, to ensure a larger proportion of ripe animals. In addition, it may be worthwhile investigating the influence of other spawning cues on calico scallops in Bermuda. Several of these, such as salinity, lunar phase, light, dissolved oxygen, pH, mechanical shock and various chemicals and food pulses have been examined for other pectinid species through correlation with field observations and more rigorous laboratory experiments (Gibbons & Castagna 1984, Starr et al. 1990, Velez et al. 1990, Desrosiers & Dubé 1993, Jamaillo et al. 1993, Couturier 1994).

In conclusion, it seems necessary for the calico scallop to have a mean gonadal index value >2 for a good response to spawning induction via thermal shocks. It can be further added that the use of gonadal indices for routine hatchery purposes provides a good snapshot of the reproductive status. However, to have a thorough understanding of gametogenic events in a specific population in relation to gonadal indices, histological assessments of reproduction in scallops is warranted in a first instance.

ABSTRACT Assortative mating and reduced hybrid fitness are typically invoked to explain the stability of hybrid zones and the specification of two closely related taxa. Such examples of mate preferences in nature, especially for broadcast free-spawning marine invertebrates, and the understanding of the underlying mechanisms responsible for this positive selection are still lacking. This study documents another example of assortative fertilization by genome *in situ* hybridization in reciprocal crosses of scallops *Chlamys farreri* and *Patinopecten yessoensis*. Females produced eggs selected sperm nonrandomly but showed significant gamete preference of conspecifics over heterospecifics, with *Chlamys farreri* females using average 89.1% of conspecific sperms and the *Patinopecten yessoensis* using average 94.3% in natural spawning conditions (temperature 17°C, salinity 31.5‰). This conspecific gamete advantage may be related to the coordinated communication between interacting gametes, and the conspecific binding genotype selection during the communicational process may also be involved. Two environmental factors, temperature and salinity were also tested to determine to what extent they affect the patterns of assortative fertilization between these two species. The result showed that temperature seemed to have more influence on assortative fertilization than salinity did. At the temperatures of 11°C, 17°C, 22°C and 26°C, the average conspecific sperms preference of *Chlamys farreri* eggs was 80.0%, 89.1%, 95.1% and 95.5% respectively, whereas at the salinity of 24‰, 28‰, 31.5‰ and 35.5‰, the average mating preference was 97.2%, 91.2%, 89.1% and 99.5% respectively. These results may have some bearings on the condition dependent alteration in the inter gamete recognition system. Alternatively, it may be simply the byproduct of different sperm tolerance ability under different conditions. The implication it may provide to hybrid production was also discussed.

KEY WORDS: scallop, assortative fertilization, *Chlamys farreri*, *Patinopecten yessoensis*

INTRODUCTION

Many theories have been developed to interpret the formation of reproductive isolation and hence the speciation process between two sympatric closely related taxa in recently years. (Palumbi & Metz 1991, Metz et al. 1994, McCartney et al. 2000, Knowlton 1993, Coyne 1992) These theories generally fall into two categories: pre- and post-zygotic barriers. Pre-zygotic barriers include mechanisms such as mate choice, genital incompatibility, spatial and temporal habitat differences and gamete incompatibility. Post-zygotic barriers, on the other hand, include mechanisms such as embryo inviability and hybrid sterility (Dobzhansky et al. 1977, Templeton 1989, Lessios 1998). Whereas, assortative fertilization or gamete preference, which is commonly regarded as a post-mating, pre-zygotic isolating mechanism, has only recently come to prominence and is increasingly accepted as another important possible barrier to hybridization and gene flow between closely related species (Bierne et al. 2002, Geyer & Palumbi 2005).

Assortative fertilization is a subtype of fertilization barrier that depends upon characteristics of the female and male such that gametes from like or unlike parents have a greater or lesser than random chance of uniting (Markow 1997). Evidence of such kind of gamete preference has been recorded in many terrestrial species such as *Drosophila* (Chang 2004, Markow 1997), crickets (Howard & Gregory 1993, Howard et al. 2002) and flour beetles (Robinson et al. 1994, Wade et al. 1995). These studies indicated without exception that conspecific sperm precedence, or biased use of sperm from males of one species might occur when a female was

exposed to sperm from males of multiple species. Possible mechanism underlying was also highly varied. In some cases, it involves compatibility of genitalia or gamete morphology. For example, in *Rhododendron*, overgrowth or undergrowth of heterospecific pollen tubes yields few hybrid embryos (Williams & Rouse 1990). In other cases, it seems to be related to functional or physiological interactions between sperms and the female reproductive tract (Markow 1997). In ladybird beetles heterospecific sperm are inactivated in storage in female reproductive tract (Katakura 1986, 1997). In *Drosophila* conspecific sperm just incapacitates or displaces heterospecific sperm during the storage. But for the broadcast free-spawning marine invertebrate, in which courtship and other complex mating behaviors that facilitate mate choice are generally non-existent, the opportunity for conspecific sperm preference and the possible mechanism has been largely ignored. To date, only few marine invertebrates have been studied for such gamete preference (Bierne et al. 2002, Palumbi 1999, Geyer & Palumbi 2005, Yung & McCartney 1994), and the possible mechanism seemed even more complicated than that of terrestrial species because of the smaller arena, the surface of gametes and the seawater between them, in which the assortative fertilization could take place. Here we present another example of assortative fertilization in external fertilization species of marine bivalves.

Hybridization between scallops *Chlamys farreri* and *Patinopecten yessoensis*, both of which are economically important shellfish species along the coast of China and Japan, has been intensively studied in recent years with the aim of improving *Chlamys farreri* germ quality from high rate of mortality and disease susceptibility (Yang et al. 2004, Zhou et al. 2005). No apparent gametic incompatibility was found in crosses of both directions between these two species either in small-scale laboratory

*Corresponding author. E-mail: qywang@public.qd.sd.cn

experiment or in larger scale breeding program (Yang et al. 2004). The putative hybrid was believed to be able to live successfully through planktonic larval stages and grow into full adults with heterosis in growth and disease resistance (Yang et al. 2004), but in some cases of hybridization, contamination was detected by genetic examination of the progeny despite much care being taken in the hybridization process (Lü et al. in press). The same phenomenon was found in the hybridization of many oyster species of *Crassostrea* (Allen & Gaffney 1993, Allen et al. 1993). Sometimes the contamination rate is comparatively high given the fact that the concentration of contaminated sperm (if exists) was much lower than that of heterospecific sperm added in hybridization. We suspect assortative fertilization may be responsible for this problem. So the aim of this study was to investigate (1) if there also exists assortative mating phenomenon between species of scallops as found in other marine invertebrates; (2) to what degree the presence of conspecific sperms affect the cross-fertilization success of interspecific sperm and (3) to what extent this assortative fertilization can be affected by environmental factors, such as temperature and salinity, so that measures may be taken to improve the scallop hybridization program.

MATERIALS AND METHODS

Scallops and Gametes

Chlamys farreri were collected from the Jiaonan area of Qingdao and *Patinopecten yessoensis* were obtained from the Dalian coast of Bohai Sea in early April 2005. Both species were transported to the laboratory and temperature and feeding were adjusted to synchronize maturation among species. All gametes were obtained by induced spawning with drying and thermal shock. Oocytes from individual females were gently sieved and placed into separate beakers after the quality was checked by light microscope and no fertilization was confirmed, counted using a Coulter cell counter and adjusted to 1×10^6 per female. Sperms from individual *C. farreri* and *P. yessoensis* were placed into separate beakers. Same treatment was conducted and adjusted to 1×10^8 per male.

Experimental Design

Four gamete mixtures were produced in the experiment: A mix of oocytes from 20 female *C. farreri* with a finally total number of 2×10^7 , a mix of oocytes from 20 female *P. yessoensis* with a finally total number of 2×10^7 , a mix of spermatozoa from 20 male *C. farreri* with a finally total number of 8×10^8 and a mix of spermatozoa from 20 male *P. yessoensis* with a finally total number of 8×10^8 . All the mixtures were then further divided into equal amount of portions, each used for one cross. This guarantees almost equal amount of gametes used in each cross and obtain a 40:1 sperm: egg ratio for the fertilization. The six crosses were conducted at temperature 17°C and salinity 31.5‰ (natural spawning condition): *C. farreri* (♀) × *C. farreri* (♂); *C. farreri* (♀) × *P. yessoensis* (♂); *P. yessoensis* (♀) × *P. yessoensis* (♂); *P. yessoensis* (♀) × *C. farreri* (♂); *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)]; *P. yessoensis* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)]. The first four crosses were used as positive controls and the later two allowed for interspecies sperm competition with equal amount of sperm from both species added. Another six sperm competition crosses were conducted the same way with the *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] under 3 levels of

temperature (11°C, 22°C and 26°C) at the salinity 31.5‰ and 3 levels of salinity (20‰, 28‰ and 35.5‰) at the temperature 17°C. The temperature was maintained by using a bio-chemical incubator (L15-2, SHELLAB) and the salinity was maintained by just adding fresh water or crude salt. All the crosses were performed in four replicates and conducted simultaneously.

Larval Development and Genetic Confirmation

Fertilization was allowed to proceed for a minimum of 50 min in each cross before all the eggs were transferred to a culture tank with a density of 30 eggs/mL. Normal culturing procedure was followed afterwards. Fertilization success was determined by examining at least 200 oocytes by light microscope at 60–90 min post-insemination. Two replicate subsamples were collected from each duplicate of the crosses for each sampling. The larvae were collected after they reached early trochophore stage and the hatching rate was also determined.

The metaphase chromosome was prepared following the procedure described by Wang et al. (1990). In brief, the embryos were exposed to 25% sea water for about 50 min after 40 min of culture in 0.04% colchicines at room temperature, then they were fixed with Carnoy fixatives (ethanol: glacial acetic acid = 3:1), and stored at -20°C until use. The fixed embryos were dissociated into fine pieces by pipetting in 50% acetic acid in a 1.5 mL microcentrifuge tube. The resultant cell suspension was dropped onto hot-dry glass slides and air-dried. Chromosome preparations were preserved in a moist chamber until use.

The GISH (genome *in situ* hybridization) procedure followed the protocol described by Leitch et al. (1994) and Takahashi et al. (1997) with some modifications. Briefly, chromosome slides were denatured in a mixture containing 75% formamide and 2 × SSC for 2–3 min at 72°C, dehydrated through an ice-cold ethanol gradient (70%, 90% and 100%), 5 min each, and air-dried. Genomic probe mixture was denatured for 5 min at 80°C, followed by immediately being put on ice for at least 10 min. The probe hybridization mix was applied to the slides and *in situ* hybridization was carried out at 37°C for 14–18 hr. The slides were washed twice in 2 × SSC, and 50% formamide at 42°C for 10 min, 1 × SSC at 42°C for 10 min and finally in 2 × SSC at room temperature for 10 min after the hybridization. Biotinylated probes were detected with fluorescein isothiocyanate conjugated avidin DCS (FITC) (VECTOR) for 1h at 37°C, counterstained with Vectashield mounting medium with propidium iodide (PI) (VECTOR) for 40 min at 37°C. Hybridization signals were detected by using a Nikon E-800 microscope equipped with the appropriate filter sets for FITC and PI.

Statistical Analysis

The percentage of hybrid larvae was determined by counting the hybrid rate in at least 200 metaphase chromosomes displayed by GISH. Two replicate subsamples were collected from each duplicate of the crosses for each sampling. These percentages were compared with random expectation by a χ^2 test of the observed number of hybrid offspring versus the number expected, if sperm use was random. The expectations were based on the measured concentrations of sperm used in each cross and the average larval hatching rate of each control. It was calculated as $EP = S1 \times H1 / (S1 + S2) \times H2$, where S1 and S2 are the respective sperm concentrations, and H1 and H2 are the respective average larvae hatching rates. Hybrid probabilities were calculated according to Palumbi (1999) as $SR / (SR + 1)$, where $SR = (L1/L2) \times (S2/S1)$. L1

TABLE 1.

The mean fertilization rates and the larvae hatching rates (\pm SE) in six crosses in natural spawning conditions (temperature 17°C and salinity 31.5‰). C: *Chlamys farreri* and P: *Patinopecten yessoensis* ($n = 8$)

Crosses	Fertilization Rate	Larvae Hatching Rate
c (♀) × C (♂)	96.5 ± 2.6	91.2 ± 1.9
C (♀) × P (♂)	95.3 ± 2.3	90.0 ± 1.9
P (♀) × P (♂)	98.0 ± 1.7	92.0 ± 1.1
P (♀) × C (♂)	96.2 ± 2.0	89.5 ± 2.2
C (♀) × [P (♂) + C (♂)]	97.4 ± 3.4	90.6 ± 2.5
P (♀) × [P (♂) + C (♂)]	94.0 ± 3.1	87.0 ± 1.6

and L2 are the number of larvae sired by heterospecific and conspecific males and S1 and S2 are the respective sperm concentrations. The percentage of hybrid larvae from each sperm competitive cross in changed conditions was also compared by a χ^2 test with that of in natural spawning conditions.

RESULTS

Fertilization and Genetic Confirmation in Control Crosses

In this part, four independent crosses with replicates were performed as positive control. Almost no difference in fertilization and the larval hatching rates was found among the crosses of *C. farreri* (♀) × *C. farreri* (♂); *C. farreri* (♀) × *P. yessoensis* (♂); *P. yessoensis* (♀) × *P. yessoensis* (♂) and *P. yessoensis* (♀) × *C. farreri* (♂). All crosses showed high levels of fertilization rates and larval hatching rates (Table 1). This is in agreement with what found by Yang in 2004. Genetic confirmation by GISH showed that all offspring from crosses of *C. farreri* (♀) × *P. yessoensis* (♂) and *P. yessoensis* (♀) × *C. farreri* (♂) were hybrid (Fig. 1b). No evident gamete incompatibility was found in these two species.

Fertilization and Genetic Confirmation In Sperm Competitive Crosses

High fertilization and the larval hatching rates were also found in the two crosses of *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] and *P. yessoensis* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] at control condition (Table 1). But genetic confirmation by GISH showed that the hybrid rates of the offspring from these crosses departed significantly from equal species contribu-

tion ($P < 0.005$) when sperm choice was available. The average hybrid rates were found to be 10.9% in *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] and 5.7% in *P. yessoensis* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] (Table 2, Fig. 2). The expected hybrid rates based on the measured concentrations of sperm used in each cross and the mean larval hatching rate of each control were 49.3% and 48.6% respectively if the sperm use was random. The hybridization probability was 0.112 and 0.055 respectively. Females of both *C. farreri* and *P. yessoensis* showed strong biased sperm use when their oocytes were exposed to mixed sperms from the two species.

Environmental Effect of Assortative Fertilization

The fertilization and larval hatching rate in crosses of *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] decreased radically when the temperature or the salinity came to extreme with a less than 60% fertilization rate and hatching rate was found at salinity 31.5‰ (the data not shown). The hybrid rate in crosses of *C. farreri* (♀) × [*P. yessoensis* (♂) + *C. farreri* (♂)] decreased significantly with increasing temperature (Table 3, Fig. 2). At the temperatures of 11°C, 22°C and 26°C, the mean hybrid rates were 20.0%, 4.9% and 4.5% respectively. These departed significantly from the mean hybrid rate obtained in natural spawning condition ($P < 0.05$). The salinity also showed significant impact on the assortative fertilization in the same manner with the mean hybrid rates of 3.8%, 8.8% and 0.5% at the salinity of 24‰, 28‰ and 35.5‰ (Table 3, Fig. 2). Temperature seemed to have more influence on assortative fertilization than salinity did.

DISCUSSION

Assortative fertilization is believed to be a very important mechanism in explaining barriers to gene flow and hybridization between many sympatric closely related species (Bierne et al. 2002). However, it is not our interest in this study to investigate whether it is also important in the speciation or the reproductive isolation between *Chlamys farreri* and *Patinopecten yessoensis*. Because the asynchronous spawning, which alone would suffice to prevent any form of hybridization in nature, has been intensively developed between these two species. The peak spawning time of *C. farreri* along north coast of China was from early May to mid June at water temperature of 16°C to 22°C (Wang et al. 1993), whereas *P. yessoensis* spawned in a colder water temperature of 8°C to 8.5°C commonly from late March to mid April (Wang et al.

Figure 1. The representative metaphase chromosomes of hybrid and pure species larvae confirmed by GISH at trochophore stage: a, shows metaphase chromosomes of hybrid larvae and b, shows metaphase chromosomes of pure species larvae of *Chlamys farreri* by biotinylated probes of *Chlamys farreri*

TABLE 2.

The mean hybrid rate (\pm SE) of sperm competition crosses in natural spawning conditions (temperature 17°C and salinity 31.5‰). The percentage was compared with random expectation by a χ^2 test of the observed number of hybrid offspring versus the number expected if sperm use was random. Hybridization probability was calculated as $SR/(SR + 1)$, SR is the average proportion of hybrids observed, corrected for differences in sperm concentration. ($n = 8$)

Crosses	Hybrid Rate (%)	Hybrid Rate Expected	Hybridization Probability	χ^2 Test (P)
C (♀) \times [P (♂) + C (♂)]	10.9 \pm 1.6	48.6	0.112	$P < 0.005$
P (♀) \times [P (♂) + C (♂)]	5.7 \pm 1.0	47.9	0.055	$P < 0.005$

1993). Instead, this study was designed to test whether this mating preference also exists in *C. farreri* and *P. yessoensis* and how much of the heterospecific sperm fertilization success was influenced at the presence of conspecific sperm.

The heterozygote deficiency obtained in these sperm competition crosses in the natural spawning condition may be explained by either (1) assortative fertilization (gamete choice); (2) differential fertilization (fertilization failure) or abortion. But the lack of heterozygote deficiency in the control crosses favors the assortative fertilization hypothesis because differential fertilization or abortion should have occurred both in control and sperm competition crosses. Moreover, abortion percentages seem insufficient to produce the observed heterozygote deficiency in the sperm competition crosses. Indeed, in the worst case, if we hypothesize that all the aborted embryos in our crosses were hybrids, then the hybrid rates won't reach the rate of expected ($P < 0.05$) when the sperm use was random. Assortative fertilization must therefore have occurred in *C. farreri* and *P. yessoensis* with *C. farreri* eggs using average 89.1% of conspecific sperms and *P. yessoensis* eggs using average 94.3% of conspecific sperms in the control condition (temperature 17°C and salinity 31.5‰). These are consistent with those of other marine invertebrates, which have recently been investigated. In sea urchins of *Echinometra oblonga* and *E. sp.C.*, an average of 87.8% *E. sp.C.* eggs were fertilized by conspecific sperms when exposed to equal amount sperm of both species (Geyer & Palumbi 2005). In the mussels *Mytilus edulis* and *M. galoprovincialis*, the total conspecific sperm use of both females was 77% when all four gametes were mixed together (Bierne et al. 2002). Conspecific sperm precedence in free spawning invertebrates shows that the simple surfaces of eggs and sperm provide ample opportunity for egg choice and sperm competition even in the absence of intricate behavior or complex reproductive morphologies.

Mechanistically, to date, only few attempts were made to investigate the mechanism of sperm biased use in free-spawning invertebrates. In sea urchins, Metz et al. (1994) demonstrated that

the specificity of fertilization between *E. oblonga* and *E. mathaei* is controlled by the interaction of the sperm protein bindin with a receptor on the egg surface. Palumbi (1998, 1999) further elucidated that different bindin alleles confer different fertilization properties in free spawning sea urchin *Echinometra mathaei*, and fertilization differences reflect male bindin genotype and are under the control of both female and male genotypes. Unfortunately, till now no detailed compositional or functional studies on sperm protein bindin were carried out in scallops, but a similar cell-cell interaction mechanism may, as well, be functioning in the assortative mating system in *Chlamys farreri* and *Patinopecten yessoensis*; if this were true, then the fact that the assortative fertilization can be influenced by environmental factors may provide another clue and possibility to further understanding of the mechanism behind the mating preference system. As shown in this study, the mean hybrid rate obtained in these crosses varied from 0.5% to 20.0% as temperature and salinity changed. It may suggest that the egg-sperm recognizing system may be slightly disturbed when fertilization condition changes. What event may take place in this recognizing system when the environmental factors change and what elements on the gamete surface may be involved in this process are now of great interest to us. But alternatively, it may just be the byproduct of different sperm tolerance under different conditions. Because the different sperm tolerance of the two species may influence the practical relative sperm concentration when the sperm competition took place. Whatever it is, assortative fertilization seemed to occur despite the temperature and salinity. Because even the highest mean hybrid rate of 20.0% at the temperature of 11°C was still likely to be the result of assortative fertilization in consideration of the same concentration of conspecific and heterospecific sperm added. Unfortunately, as no control data of hatching rate was available in each cross under these changed conditions, we can't speculate further.

Although much remains unknown about the underlying mechanism of assortative mating system until now, the phenomenon itself has much implication for our practical hybrid production. In

the hybridization of *Chlamys farreri* and *Patinopecten yessoensis*, especially in a large scale breeding program, conspecific sperm contamination can cause problems that affect the efficiency of hybridization. The contamination can come from many sources such as: careless handling of fishery tools, sperm from natural seawater via water supply system and a small proportion of her-

maphroditic individuals in scallops. In some cases, the heterospecific sperm was added prior to the female spawning with the intention to decrease the chance of self fertilization. But it commonly results in little amelioration. From the present study, we know that the preaddition of heterospecific sperm before spawning won't necessarily decrease the self fertilization rate because of the conspecific sperm precedence. So more care, such as parent scallops selection or more careful handling of fishery tools, should be taken prior to or during the hybridization to minimize the sperm contamination. Another implication we can get from the study is that, because environmental factors can affect the assortative fertilization in the competitive fertilization system, some measurements, such as fertilization at lower temperatures, fertilization in a optimum water salinity and pH value can be taken to increase the hybrid rate in hybridization, if contamination cannot be avoided.

GENOTYPE-DEPENDENT SURVIVAL, GROWTH, AND PRODUCTION IN CULTURED BLUE MUSSELS, *MYTILUS* SPP.: RESULTS OF A RECIPROCAL SEED TRANSFER EXPERIMENT

R. W. PENNEY,* M. J. HART AND N. D. TEMPLEMAN

Department of Fisheries and Oceans, Science Branch, P. O. Box 5667, St. John's, Newfoundland, Canada, A1C 5X1

ABSTRACT A reciprocal mussel seed transfer experiment was conducted involving two farm sites (Charles Arm and Thwart Island) whose seedstocks differed significantly in their respective compositions of *Mytilus edulis* L., *M. trossulus* Gould and hybrids. Electrophoretic variation at the mannose phosphate isomerase (*Mpi*) enzyme locus was used to classify the two species and their hybrids. Survival and growth in shell length, wet weight, shell weight and flesh weight were monitored over a 14-mo period. Both stock groups originating from Thwart Island seed (TI reared on its native site and the transferred TI-X stock) and the transferred stock group originating from Charles Arm seed (CA-X) showed no evidence of genotype-dependent variability in survival whereas, in the Charles Arm seed reared on its native site (CA), the proportion of *M. edulis* declined in relation to *M. trossulus*. There was no evidence of either a survival advantage or disadvantage in hybrids. After 14 mo, both transferred stocks (CA-X and TI-X) had comparatively higher frequencies of *M. edulis* and hybrids and lower frequencies of *M. trossulus* than did their respective nontransferred stocks (CA and TI) indicating a significant genotype \times site interaction effect on survival. Significant species, stock, stock \times time, species \times time and stock \times species \times time effects on shell length, wet weight, shell weight and flesh weight occurred. Intrastock growth rates of *M. trossulus* were lower than *M. edulis* and hybrids for shell length (3 of 4 stocks), and for the 3 weight variables, wet weight, shell weight and flesh weight (4 of 4 stocks). These results support the conclusion that growth is genotype-dependent in rope-cultured mussel populations and that these differences in weight growth favoring *M. edulis* are maintained when such stocks are transferred to other sites. Mussel biomass (kg m^{-1}) was similar for the CA, CA-X and TI-X stock groups and lower for the TI stock group. Rates of production (wet weight) over the 14-mo growout period were similar for the CA, CA-X and TI stock groups and significantly higher for the TI-X stock group. In both stock groups originating from Thwart Island seed (TI reared on its native site and the transferred TI-X stock), the intrastock rates of production of *M. edulis* and hybrids were significantly greater than sympatric *M. trossulus*. However, in the transferred Charles Arm stock (CA-X), the rates of production were similar in *M. edulis* and *M. trossulus* and significantly greater in hybrids. In the Charles Arm stock reared on its native site (CA), the rate of production of *M. trossulus* was significantly greater than either *M. edulis* or hybrids. We conclude *M. edulis* and hybrids have intrinsically greater rates of weight growth, but not necessarily length growth, than does *M. trossulus*. Neither *M. edulis* nor *M. trossulus* nor hybrids have consistently greater rates of survival or production in suspended rope culture. These results are discussed in the context of a directed seed-stocking program involving the transfer of *M. edulis* seedstocks to sites whose native stocks have a high *M. trossulus* component as a means to enhance commercial mussel production within the *M. edulis*-*M. trossulus* hybridization zone in Atlantic Canada.

KEY WORDS: *Mytilus*, genotype-dependent, reciprocal transfer, survival, growth, production

INTRODUCTION

Two mytilid mussel species, *Mytilus edulis* and *M. trossulus*, are endemic to northeastern North America. They are sympatric throughout a broad overlapping distributional zone extending from Newfoundland through the Gulf of St. Lawrence, along the Atlantic coast of Nova Scotia and into the northeastern United States (McDonald et al. 1991, Mallet & Carver 1992, Bates & Innes 1995, Penney & Hart 1999, Rawson et al. 2001). Localized mussel populations are typically composed of mixtures of the two species, often varying widely in relative frequency between adjacent sites in close proximity to each other (Mallet & Carver 1992, Bates & Innes 1995, Penney & Hart 1999). Indeed, nearby sites often display intersite genetic heterogeneity on a magnitude scale comparable to sites much farther apart (Penney & Hart 1999). The two species also readily hybridize (Saavedra et al. 1996, Comesaña et al. 1999, Penney & Hart 2002a, Penney et al. 2002) forming a highly diverse, genetically heterogeneous hybridization zone.

Survival is genotype-dependent in rope-cultured populations on farm sites within the hybridization zone (Penney & Hart 2002a). Thus, temporal genetic heterogeneity is likely a significant contributing factor to the extensive genetic population structuring found throughout the hybridization zone (Penney & Hart 1999). Furthermore, growth in shell length, wet weight, shell weight and

flesh weight are also genotype-dependent with growth rates for these weight variables being greater in *M. edulis* than *M. trossulus*, whereas growth rates in hybrids are typically intermediate between the two (Penney et al. 2002). Thus, genotype-dependent processes may be a significant contributory factor influencing production variability among mussel farms (Penney & Hart 2002a). Currently, many mussel farms within the hybrid zone, particularly sites in Newfoundland, use seed collected from their native sites with little regard or knowledge of their species composition. Because the relative species composition of the native seedstocks at these sites may differ dramatically (Penney & Hart 1999), this practice may contribute to the highly variable intersite growth and production indices throughout the industry. A recommendation has been made that growout of transplanted seed derived from unspecific or high-ratio *M. edulis* stocks should increase farm site production and reduce intersite variability in comparison with the use of seed collected on-site from indigenous mixed-species stocks (Penney et al. 2002). The greatest improvement in production would be anticipated at sites whose native seedstocks are primarily *M. trossulus*.

However, this recommendation has been advanced as a result of work carried out with indigenous seedstocks reared on their native sites. As Penney et al. (2002) pointed out, concern exists that our present state of knowledge of relationships among genetic heterogeneity, environmental variability and the intrinsic range of adaptive physiological flexibility in mussels (Hawkins & Bayne

*Corresponding author. E-mail: penneyra@dfo-mpo.gc.ca

1992) is inadequate to reliably predict the subsequent production performance of transplanted seedstocks. Yet, achieving predictable results from intersite seed transfers is key to successful implementation of a directed seed transplantation program by industry to increase commercial production. Implicit in the above recommendation are the assumptions that (a) mussel performance indices, which control production (e.g., survival and growth) are significantly controlled by stock genetics and thus are predictable when transferred among sites and (b) the range of natural intersite environmental variability over geographic scales wherein intersite stock transfers are practically feasible to industry does not exceed the intrinsic scope of adaptive flexibility within mussel populations.

In the various mussel species being commercially cultivated, production indices are affected by variable growth and survival, both of which are known to be significantly influenced by stock-related factors (i.e., genetic variability; Fuentes et al. 1992, Stirling & Okumus 1995, Mallet & Carver 1995, Myrand & Gaudreault 1995 and site-related environmental variability; Dickie et al. 1984, Mallet & Carver 1989, Mallet et al. 1987). However, supporting evidence is somewhat equivocal concerning the comparative survival and growth of mussel stocks when transplanted versus when reared indigenously. There is some supporting evidence that interstock mortality differences are maintained when mussel stocks are transferred to new sites (Mallet et al. 1990, Myrand & Gaudreault 1995) suggesting that among-site survival variation is more influenced by stock genetics than environmental factors. In a series of experimental stock transfers in Nova Scotia, Mallet et al. (1990) noted survival rates in several stocks were unaffected by transfer leading to their conclusion that these stocks seemed insensitive to the environmental gradient. However, Dickie et al. (1984), Mallet et al. (1987) and Mallet & Carver (1989) concluded variation in mussel growth rates were mainly attributable to site-related environmental effects rather than stock (genetic) effects.

On a practical level, the mussel culture industry based in Prince Edward Island has successfully transplanted mussel seed from designated seed production sites to other growout sites over geographic scales of several kilometers. However, in Prince Edward Island, both the donor and recipient sites have indigenous mussel stocks that are virtually unispecific *M. edulis* (Mallet & Carver 1999). Similarly, for other mussel species and locations worldwide where commercial industry routinely transfers seedstocks successfully, (e.g., *M. galloprovincialis*) in Spain (Fuentes et al. 1994) and *Perna canaliculatus* in New Zealand (Alfaro & Jeffs 2003), these are areas with relatively low interstock genetic diversity. However, within the Atlantic Canadian hybrid zone, it has previously been observed that pure *M. edulis* stocks transferred from different locations can vary substantially in terms of tissue and shell growth, mortality and production (Mallet & Carver 1999). Past stock transfers involving more genetically heterogeneous seed populations have sometimes yielded unexpected growth and mortality patterns (Mallet & Carver 1989; Johannesson et al. 1990, Kautsky et al. 1990), which would be highly undesirable in a commercial context. Mallet and Carver (1999) have noted that transferred pure *M. edulis* stocks may not necessarily outperform a local mixed-species stock suggesting the possibility of significant localized adaptations in resident stocks. Interpretation of these sometimes conflicting results has been complicated by inadequate knowledge of stock genetic composition leading to concern regarding the predictability of subsequent survival and growth indices in transplanted seedstocks. This is especially so when the candidate seed-

stock for transplanting is genetically quite different from the indigenous stock (e.g., a unispecific *M. edulis* seedstock when transplanted to a predominately *M. trossulus* site). Because high-ratio *M. trossulus* populations are very common in most areas outside the general vicinity of Prince Edward Island, this concern is of significant importance to further industry development in the Atlantic Canadian hybrid zone.

In this study, we attempt to address this issue. We have conducted a reciprocal transfer experiment involving two genetically heterogeneous seedstocks, one a high ratio *M. edulis* stock and the other a relatively higher ratio *M. trossulus* stock from within the *M. edulis*-*M. trossulus* hybridization zone in Notre Dame Bay, Newfoundland. A suitable unispecific *M. edulis* stock was unavailable for intersite transfers within our geographic area under current seedstock transfer regulations, so we had to content ourselves with a known local high-ratio *M. edulis* stock. We compare the growth, survival and production patterns of each stock and of the *M. edulis*, *M. trossulus*, and hybrid constituents within each of the resulting four stocks (two reared indigenously, two reciprocally transferred) over a 14-mo period of rope culture at two farm sites. Specifically, we test the hypothesis that growth, survival and production rates of *M. edulis* and possibly hybrids as well are intrinsically higher than sympatric *M. trossulus* and that these intrastock differences are maintained when stocks are transplanted to other sites. The results are used to determine whether the substitution of indigenous *M. trossulus* seedstocks through intersite transfer of predominately *M. edulis* seedstock for growout can be supported as a viable approach to enhance commercial farm production.

METHODS

Previously, mussel populations at two farm sites in Notre Dame Bay (Charles Arm and Thwart Island), Newfoundland, were identified as predominately *M. edulis* and *M. trossulus* respectively (Penney & Hart 2002a). In August 2000, a reciprocal transfer experiment was set up involving seed collected on ropes suspended subtidally at both sites. Four seed groups were monitored for survival and growth over a 14-mo period: Charles Arm seed kept at Charles Arm (CA), Charles Arm seed transferred to Thwart Island (CA-X), Thwart Island seed kept at Thwart Island (TI), and Thwart Island seed transferred to Charles Arm (TI-X). Seed mussels from each stock were mechanically de-clumped to ensure randomization and then sleeved in standard commercial plastic mesh using current industry husbandry practices for rope culture of blue mussels. Seed mussel sleeves from each donor stock were then either placed in the water at Charles Arm or transferred to Thwart Island. Each sleeve was 1 m in length and was vertically suspended at 0.5 m intervals from horizontal mainline ropes with flotation sufficient to ensure stable suspension at depths of approximately 4–6 m.

Three replicate sleeves were taken from each donor seed stock for laboratory analysis at the time of sleeving. On subsequent sample dates (November 2000, May 2001 and October 2001), three replicate sleeves were retrieved from each of the four stock groups on their respective farm sites. All the mussels were removed from measured sections of each sleeve and counted. On each sample date, one hundred individuals were randomly selected from each sleeve per stock group and measured for shell length, drained wet weight, shell weight and flesh weight (total of 300 from each site \times group combination). Shell length was measured with digital callipers (Mitutoyo, Aurora, IL, USA). Wet weights

were obtained after opening the shell valves and allowing the shell cavity to drain on paper towel. Hepatopancreas tissue was excised from each selected mussel, lyophilized and stored at 5°C for later allozyme analysis. The remaining soft tissues were then removed and shell weights were obtained after drying overnight. Flesh weights were calculated by difference between wet weight and dry shell weight.

For allozyme analysis of mannose phosphate isomerase (*Mpi*, EC 5.3.1.8), a small amount of freeze-dried material was ground to a fine powder with 0.5 M Tris HCL pH 8.0 buffer containing 20% glycerol and 0.2% NAD. Subsequent electrophoresis and staining on cellulose acetate plates followed the general procedure of Herbert and Beaton (1989) for the mannose phosphate isomerase locus, although a constant current of 2 mA per plate was used during the electrophoretic runs. Allele nomenclature is similar to that used by previous authors (Koehn et al. 1984, McDonald & Koehn 1988). Individual mussels were classified as *M. edulis*, *M. trossulus* or their hybrids based on their *Mpi* electrophoretic patterns according to previously published references for North American populations (Varvio et al. 1988, McDonald et al. 1991).

Survival over time was calculated as the difference in mean number of mussels sleeve⁻¹ on each sample date compared with the initial sample at the time of sleeving. In this context, changes in survival do not distinguish between changes caused by mortality versus dropoff from the culture gear. Rate of production was defined as the rate of change in wet weight between the initial and final sleeve weights where initial and final sleeve weights were calculated as the mean individual mussel wet weight multiplied by the number of mussels present. Rate of production was then calculated from the formula: Production = (final wet weight-initial wet weight)/initial wet weight. All subsequent statistical analyses were run with the SAS software system (SAS Institute Inc. 1988). Interstock and intergenotype differences in initial frequency distributions and survival were compared with the chi-square statistic. ANOVA were used to compare interstock and intergenotype differences in initial size of seed mussels and production over time. Tukey tests were applied to determine which comparisons were statistically significant. ANCOVA (homogeneity of slopes models) were used to compare interstock and intergenotype differences in growth.

RESULTS

Survival

In August 2000, mussel seed from the two donor sites, Charles Arm (CA) and Thwart Island (TI), were sleeved volumetrically after de-clumping to ensure randomization of all stock. The initial seed sleeving density was 2.44 l m⁻¹ and 2.47 l m⁻¹ for CA and TI seedstocks respectively. These differences were not significant (Student's *t*-test, $P > 0.05$). The frequency distribution of *M. edulis*, *M. trossulus* and their hybrids differed significantly in the two seedstocks at the time of sleeving. The initial CA seedstock was comprised of 76.2% *M. edulis*, 7.4% *M. trossulus* and 16.4% hybrids. In comparison, the initial TI seedstock was 54.7% *M. edulis*, 26.7% *M. trossulus* and 18.6% hybrids (χ^2 , $P < 0.001$) (Fig. 1). Over the 14-mo growout period, genotype-dependent survival patterns became evident in the CA stock but not in the CA-X, TI or TI-X stocks (Fig. 2). In the CA stock, the frequencies of *M. edulis* and hybrids declined to 65.9% and 14.7% respectively, whereas the frequency of *M. trossulus* increased to 19.4% (χ^2 , $P < 0.001$). After 14 mo, the frequencies of *M. edulis*, *M. trossulus* and their

hybrids were 70.2%, 20.4% and 9.4% in the CA-X stock; 48.3%, 35.0% and 16.7% in the TI stock and 57.5%, 23.1%, and 19.4% in the TI-X stock respectively. However, these frequency changes of *Mytilus* genotypes over the 14-mo growout period in the CA-X, TI and TI-X stocks were not significant compared with their respective initial Charles Arm or Thwart Island seedstock (χ^2 , $P > 0.05$).

Mean survival over the 14-mo growout period was significantly lower in the transferred Thwart Island stock (TI-X, 32.6%) than for either of the stocks derived from Charles Arm seed (nontransferred CA, 43.7%; transferred CA-X, 46.8%) or the nontransferred stock from Thwart Island seed (TI, 48.1%) (Fig. 2). Interstock differences in mean survival were not significant among the CA, CA-X and TI stocks (ANOVA, $P > 0.05$). Comparison of the genotypic frequency distributions of the CA versus CA-X stocks and the TI versus TI-X stocks after 14 mo gave evidence of a significant site effect on the survival of the respective *Mytilus* genotypes. After 14 mo, the genotypic frequency distributions of the CA and CA-X stocks had significantly diverged from each other (χ^2 , $P < 0.001$) and the TI and TI-X stocks were also significantly different (χ^2 , $P < 0.006$). In both cases, the transferred stocks (CA-X and TI-X) had comparatively higher frequencies of *M. edulis* and hybrids and lower frequencies of *M. trossulus* than did their respective nontransferred stocks (CA and TI). This provides evidence of a significant site \times genotype interaction effect on survival among the three *Mytilus* genotypes.

Growth

When sleeved in August 2000, mean shell length, wet weight, shell weight and flesh weight of seedstocks from both donor sites differed significantly (Tukey, $P < 0.05$) (Table 1). For all four variables, CA seed mussels were larger than the TI mussels. Within the CA seedstock, there was no evidence of species-related differences in either of the four variables. However, within the TI seedstock, *M. trossulus* mussels were significantly larger than *M. edulis* and hybrids in terms of shell length, wet weight and flesh weight, but interspecies differences in shell weight were not significantly different.

Variability in all 4 growth variables (shell length, wet weight, shell weight and flesh weight) were all significantly related to species, stock and growout time (ANOVA, Table 2). The interaction effects of species \times time and stock \times time were also significant for all four variables, whereas the interaction effect of stock \times species \times time was significant for the three weight variables but not shell length. The interaction term, species \times stock, was not significant for any of the four variables. The goodness of fit (R^2) ranged from 0.66–0.72 for the four models.

Analysis of variance homogeneity of slopes models revealed that, over the 14-mo growout period, the two stocks raised at the Charles Arm site (CA and TI-X) consistently grew faster than did the two stocks reared at Thwart Island (TI and CA-X) (Fig. 3). At Charles Arm, the shell length slope for the transferred TI-X was significantly greater than the slope of the indigenous CA stock but slopes for all three weight variables were not significantly different between the two stocks. At Thwart Island, slopes for the transferred CA stock and the indigenous TI stock were not significantly different for shell length but, for all three weight variables, the respective slope for the CA-X stock was significantly greater than the TI stock.

Analysis of variance homogeneity of slopes models were subsequently used to elucidate the interaction effects involving spe-

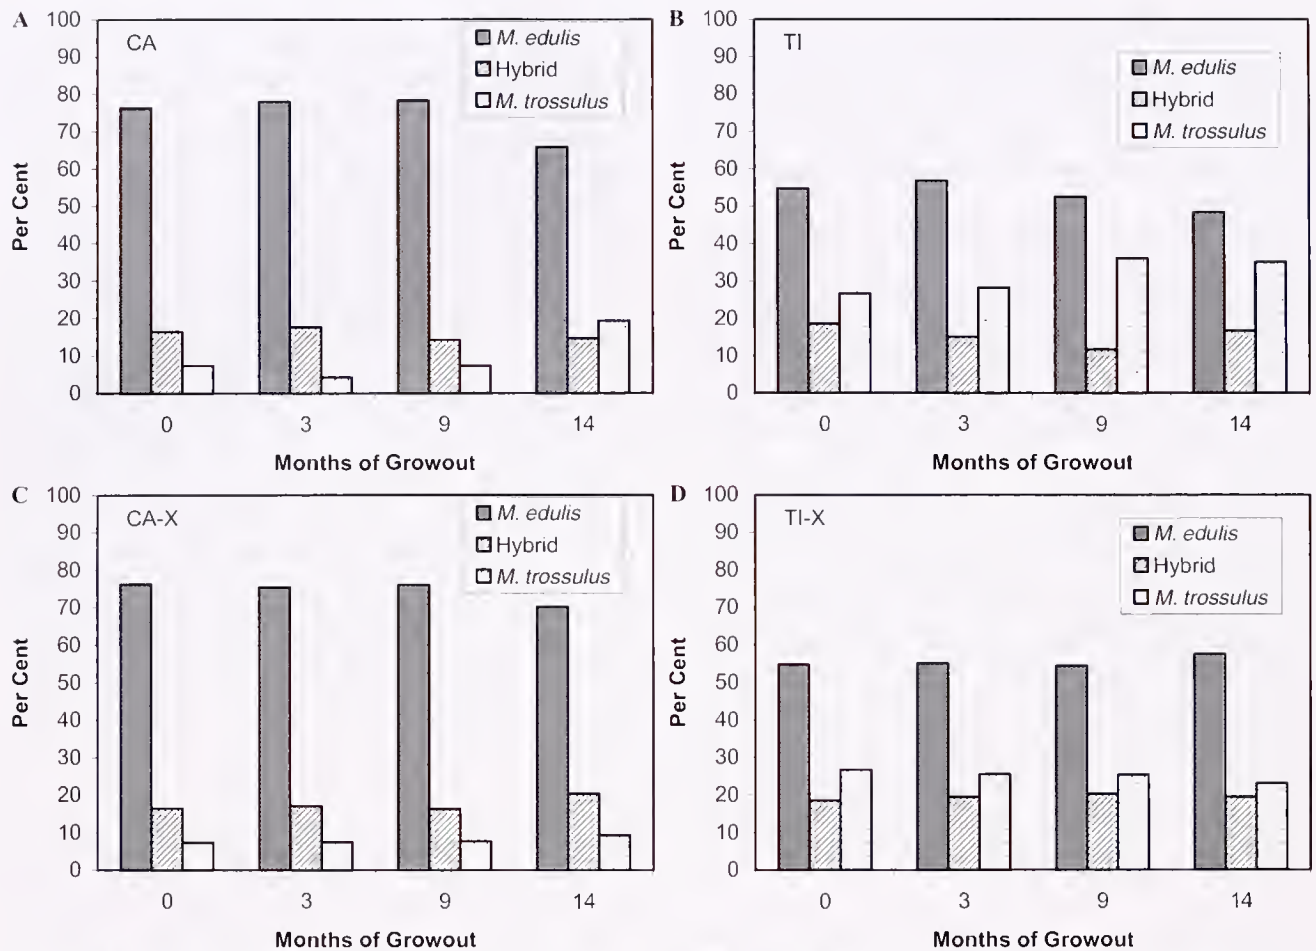

Figure 1. Mean species composition of each of the four stock groups (percent *M. edulis*, *M. trossulus*, and their hybrids) on four sampling dates during the 14-mo growout period determined from three replicate sleeves on each sample date.

cies within stocks over the 14-mo growout period. For shell length, within-stock model slopes for *M. trossulus* were significantly lower than both *M. edulis* and hybrids for all but the CA-X stock (Fig. 4). A consistent within-stock interspecific pattern emerged for all three weight variables. In each case, within-stock model slopes for wet weight (Fig. 5), shell weight (Fig. 6) and flesh weight (Fig. 7), were significantly lower for *M. trossulus* than for *M. edulis* and hybrids. For all four variables, slopes of *M. edulis* and hybrids were not significantly different from each other.

Production

After 14 months, the mussel biomass (mean wet weight \times number of survivors) of the CA CA-X and TI-X sleeves ranged from 4.26–4.49 kg m⁻² but were not significantly different (Table 3).

TABLE 1.

Initial size comparison of mussel seed from the two donor sites (Charles Arm, CA and Thwart Island, TI) at the time of sleeving: (a) full stock basis, and (b) and (c) by species within site. Numbers with different superscripts are significantly different within columns for each of (a), (b) and (c), $P < 0.05$ (Tukey multiple range test).

Figure 2. Comparative survival of the four stock groups over the 14-mo growout period. Plotted points are means ± 2 SE of counts on three replicate sleeves on each sample date.

TABLE 2.

Analysis of variance (ANOVA) test results for species (*M. edulis*, hybrid, and *M. trossulus*) and stock (CA, CA-X, TI, and TI-X) variation over the 14-month growout period for shell length, wet weight, shell weight, and flesh weight.

Variable	F Value							R ²
	Species	Stock	Time	Sp. × Time [‡]	Sp. × Stk. [‡]	Stk. × Time [‡]	Stk. × Sp. × Time [‡]	
Shellen	7.76**	60.58***	5403.99***	25.81***	1.32	19.92***	1.99	0.69
Wetwgt	4.79**	15.42***	5257.92***	64.28***	0.96	75.71***	5.68***	0.70
Shellwgt	3.24*	11.08***	5479.08***	93.39***	0.74	96.29***	8.46***	0.72
Fleshwgt	5.65**	17.71***	4470.41***	38.21***	1.17	53.53***	3.45**	0.66

Numbers without superscript are not significantly different, $P > 0.05$; *** $P < 0.0001$; ** $P < 0.01$; * $P < 0.05$. ‡sp. = species, stk = stock, etc.

Mean mussel biomass of the TI stock group was significantly lower than either of the other three stock groups. The rate of production, defined as the increase in mussel wet weight m^{-1} of sleeve, was not significantly different among the CA, CA-X and TI stock groups but was significantly greater in the TI-X stock group (Table 3). Within both stock groups originating from the Thwart Island seedstock (TI and TI-X), *M. edulis* and hybrids had significantly greater production rates than *M. trossulus*. However, in the CA-X stock group, hybrids had a higher rate of production than either of the other two species. In the CA stock group, *M. trossulus*

had a significantly higher rate of production than either *M. edulis* or hybrids. Thus, neither *M. edulis* nor *M. trossulus* nor their hybrids consistently exhibit greater rates of production within all stock groups.

DISCUSSION

Whether being considered from an individual farm or industry-wide perspective, the commercial industry objective is to maximize on-site production, while reducing production variability

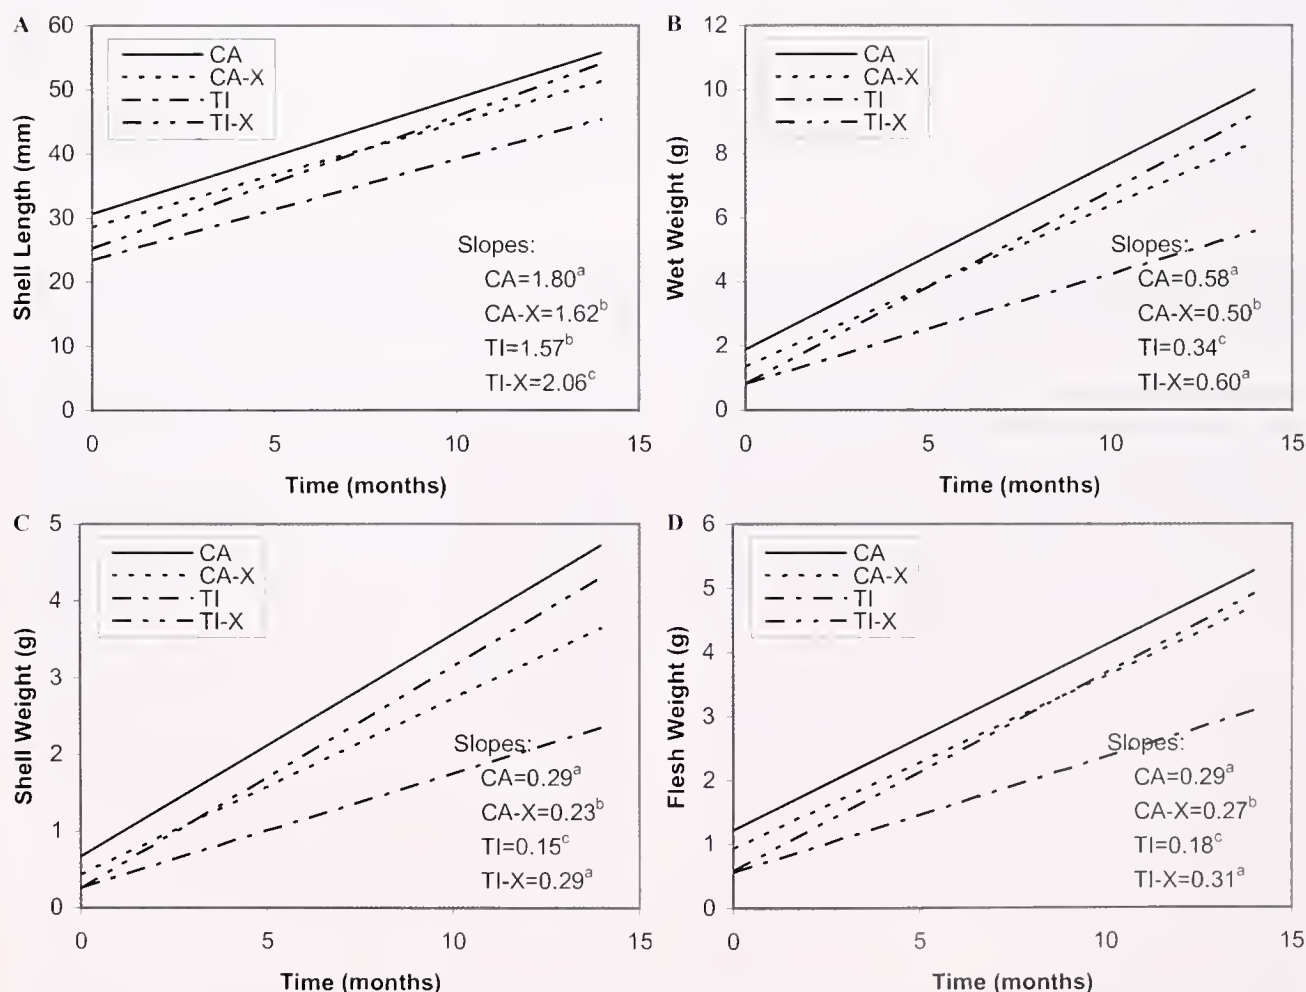

Figure 3. Comparative intersite growth in shell length, wet weight, shell weight, and flesh weight of each of the four stock groups over the 14-month growout period. Lines are fitted to the respective linear regression equations for each stock group over time. Different superscripts denote statistical significance between slopes (ANOVA homogeneity of slopes model, $P < 0.05$)

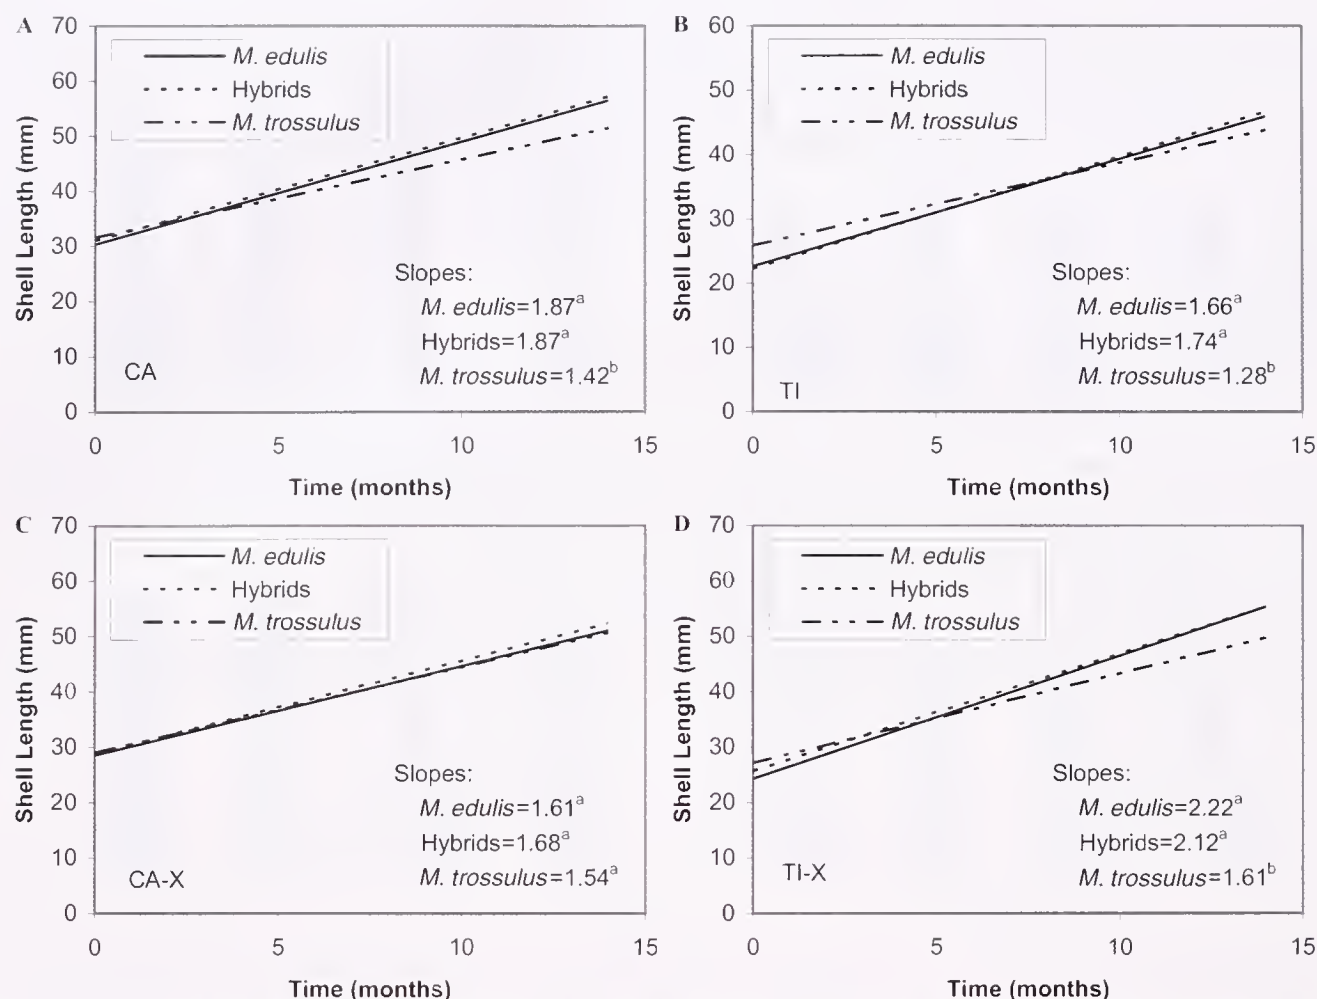

Figure 4. Comparative intrastock growth in shell length of *M. edulis*, *M. trossulus*, and their hybrids over the 14 mo growout period for each of the four stock groups. Lines are fitted to the respective linear regression equations of shell length over time for each stock group. Different superscripts denote statistical significance between slopes (ANOVA homogeneity of slopes model, $P < 0.05$).

within and among farm sites. Genetic heterogeneity within and among sites can be a highly significant source of phenotypic variability in survival, growth and shell morphology (Penney & Hart 1999; Penney & Hart 2002a, Penney et al. 2002), all of which affect commercial industry production. At sites within mussel hybrid zones, genetic heterogeneity and phenotypic variability are both typically much greater than in areas occupied by single species (Gardner 1996). Because *M. edulis* exhibits faster growth in comparison with *M. trossulus* (Penney et al. 2002), it has been recommended that commercial production indices within the hybrid zone may be improved and intrasite and intersite variability reduced if industry were to convert to use of seed from unspecific or at least high-ratio *M. edulis* seedstock(s) replacing their present practice of seed collection from a multitude of sites, which often vary widely in species proportions (Penney et al. 2002). This would be especially beneficial at sites whose native mussel populations are predominately *M. trossulus*.

Commercial success of such a proposition depends on the relatively greater growth performance of *M. edulis* versus *M. trossulus* when stocks are grown on their native sites (Penney et al. 2002) being maintained when transplanted and for this growth differential to translate into increased production at the recipient site. The present work tests this proposition by assessing the relative

growth, survival and production dynamics of sympatric cohorts of these two species and their hybrids in a reciprocal transplant experiment. With respect to survival, we confirm earlier observations (Mallet & Carver 1995; Penney & Hart 2002a) that genotype-dependent survival patterns occur among the various *Mytilus* genotypes in rope-cultured mussel populations within the Atlantic Canadian hybrid zone. However, these patterns do not consistently favor survival of either *M. edulis* or *M. trossulus* or their hybrids at all sites. In other words, survival is influenced by a significant stock \times site interaction effect. It is also interesting to note that genotype-dependent selection favoring *M. trossulus* occurred in the Charles Arm stock reared on its native site. However, in a similar growout experiment involving an earlier year class of Charles Arm seed grown at the same site (Penney & Hart 2002a), there was no evidence of any selective survival pattern at the *Mpi* locus although overall survival of that Charles Arm year class was lower than the Thwart Island stock at that time. We infer from these results that genotype-dependent survival patterns are also temporally variable among year classes within the same stock, possibly indicative of a genotype-dependent interaction with changing environmental conditions. Thus, in a commercial context, year-class to year-class survival patterns within rope-cultured mussel populations are currently somewhat unpredictable. Because

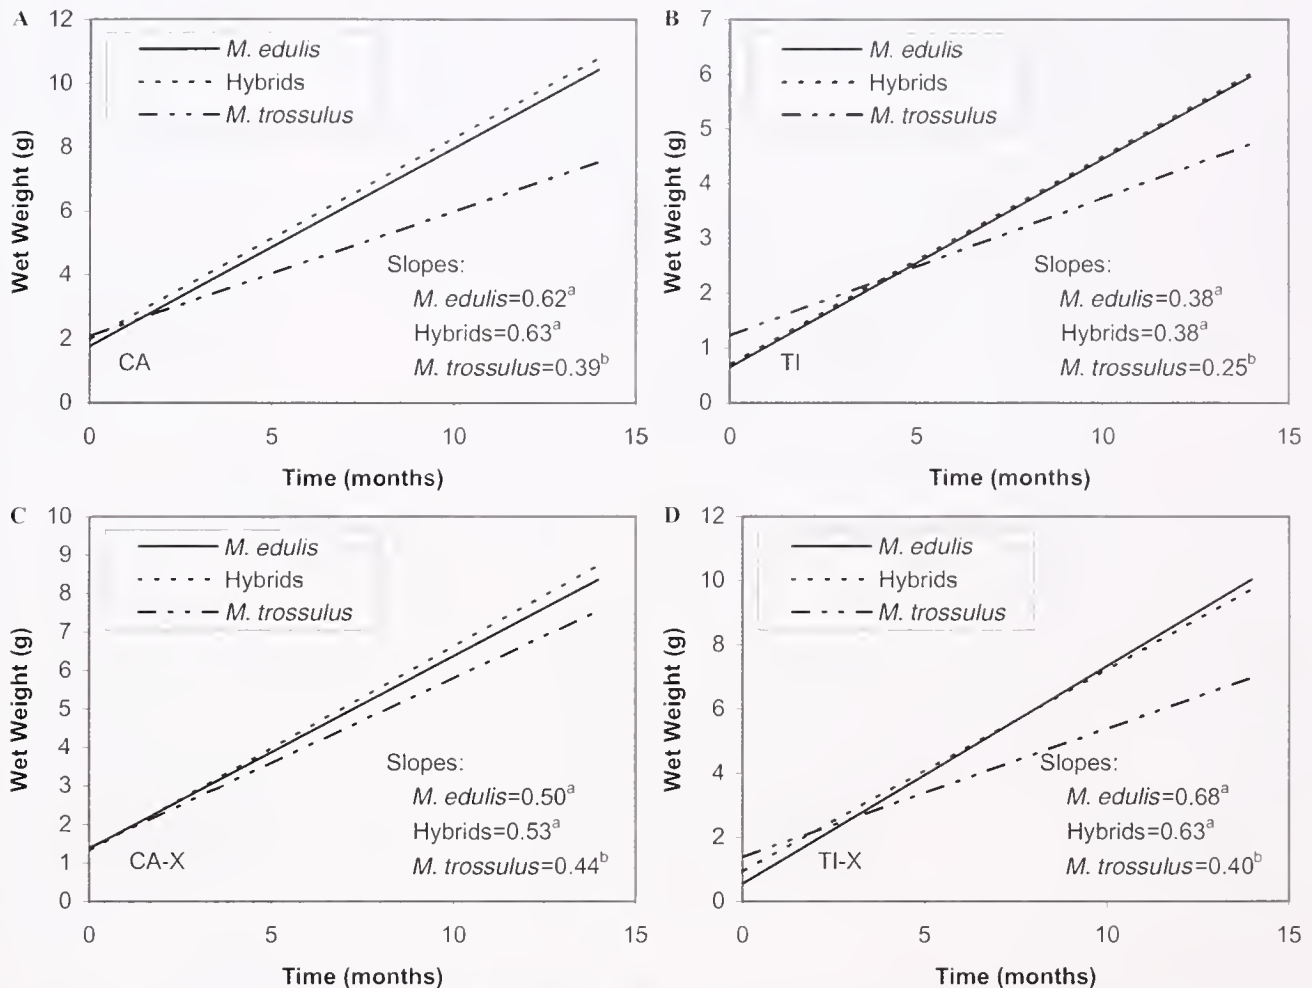

Figure 5. Comparative intrastock growth in wet weight of *M. edulis*, *M. trossulus*, and their hybrids over the 14 mo growout period for each of the four stock groups. Lines are fitted to the respective linear regression equations of wet weight over time for each stock group. Different superscripts denote statistical significance between slopes (ANOVA homogeneity of slopes model, $P < 0.05$).

variable survival patterns may strongly affect production rates, this has important consequences for mussel aquaculture development within the hybrid zone.

The present results support earlier observations (Penney et al. 2002) that growth rates in wet weight, shell weight and flesh weight, but not necessarily growth in shell length, are typically greater in *M. edulis* and hybrids than in *M. trossulus*. We further conclude these genotype-dependent differences are maintained when stocks are transplanted to other sites. But, the intrinsically greater weight growth rates of *M. edulis* and hybrids do not necessarily translate into greater production performance in comparison with *M. trossulus*. Our analysis of production performance did not find either *M. edulis* or *M. trossulus*, or their hybrids consistently had comparatively higher rates of production in all cases. *M. edulis* and hybrid production rates were higher than *M. trossulus* in two of four stock groups, *M. edulis* and *M. trossulus* production rates were similar in a third group, and the *M. trossulus* production rate was greater than either of *M. edulis* or hybrids in the fourth group. The lower rates of production of *M. edulis* within the two stock groups originating from the Charles Arm seedstock (CA and CA-X) and the relatively high production rate of *M. trossulus* within the CA stock group was largely because of the relatively lower survival of *M. edulis* within these two groups and to the

relatively greater survival of *M. trossulus* in the CA stock group. The greater wet weight of the Charles Arm seed compared with Thwart Island seed at the time of sleeving also may have played a part in the comparatively lower production rates of their respective stock groups. Thus, we conclude our results do not support the proposition that *M. edulis* has intrinsically higher rates of production than *M. trossulus*. Therefore, a directed seed transfer program transplanting *M. edulis* stocks to sites whose native seedstocks are mostly *M. trossulus* will not necessarily result in increased rates of production on such mussel farms.

Lower survival rates of the *M. edulis* cohort compared with *M. trossulus* in mixed-species stocks has previously been reported from Lunenburg Bay in Nova Scotia (Mallet & Carver 1995). However, the relatively poor survival of *M. edulis* within stocks originating from Charles Arm seed is inexplicable at this point. This is especially so in light of the fact there was no evidence of genotype-dependent selection at the *Mpi* locus in a previous year class reared from seed to harvest size at Charles Arm using identical husbandry techniques and mussels of approximately the same age (Penney & Hart 2002a). *M. edulis* and *M. trossulus* are known to differ in their relative tolerance to temperature and salinity variations, with *M. trossulus* considered to be adapted to relatively colder, lower or more variable salinity environments (Väinölä &

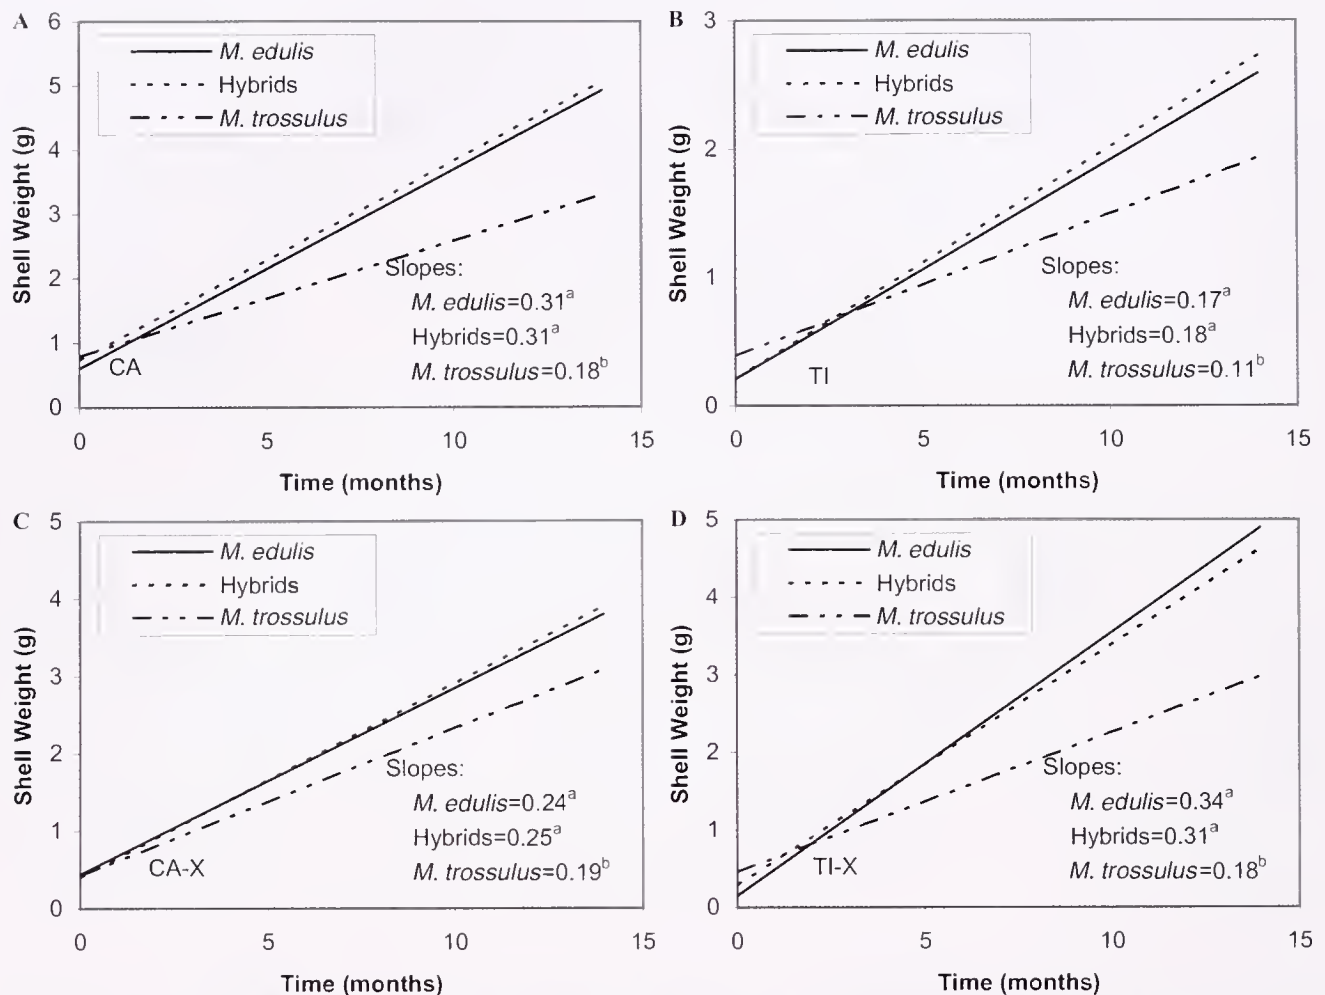

Figure 6. Comparative intrastock growth in shell weight of *M. edulis*, *M. trossulus*, and their hybrids over the 14 mo growout period for each of the four stock groups. Lines are fitted to the respective linear regression equations of shell weight over time for each stock group. Different superscripts denote statistical significance between slopes (ANOVA homogeneity of slopes model, $P < 0.05$).

Hvilson 1991, Mallet & Carver 1995, Rawson et al. 2001). However, it should be emphasized at this point that, although the transfer of stocks across large environmental gradients is known to have potentially significant deleterious effects on mussel survival (Theisen 1978, Kautsky et al. 1990, Johannesson et al. 1990), the two sites used in the present work are both located in the same bay and subjected to similar thermal and salinity regimes. Thus, no obvious strong environmental gradient exists between the Thwart Island and Charles Arm sites, which might offer a likely explanation for the results of the present study.

Genotype-dependent mortality has previously been reported in mixed *M. edulis*-*M. trossulus* stocks (Pedersen et al. 2000) and temporal and/or stock-related variability in its expression may be commonplace within Atlantic Canadian mussel stocks. This is evidenced by a reciprocal seed transfer experiment by Myrand and Gaudreault (1995) who found that four mussel stocks originating from nearby sites in the Magdalen Islands differed dramatically in resistance to summer mortality despite all being predominately *M. edulis* (Tremblay et al. 1998). In a subsequent transfer experiment, it was noted the resistant stock suffered a significant decrease in degree of heterozygosity when transferred to other nearby sites leading to the hypothesis that more heterozygous individuals migrate to the outer regions of sleeves faster than more homozygous

individuals where they are more prone to drop-off caused by turbulence (Tremblay et al. 1998). However, Penney and Hart (2002a) evaluated multilocus heterozygosity at five of the same loci used by Tremblay et al. (1998) and found no evidence of temporal changes in heterozygosity in rope-cultured populations of either the Charles Arm or Thwart Island stocks. Thus, similar heterozygosity-fitness relationships in the Charles Arm stock appear an unlikely explanation for the relatively poor survival of the *M. edulis* component at Charles Arm.

Clearly, some factor other than simply genotypic variability at the *Mpi* locus results in significant intrastock and temporal survival variability in mixed *M. edulis*-*M. trossulus* stocks, although that unknown factor does seem linked to allelic variability at the *Mpi* locus. Allelic variability at several allozyme loci are known to be correlated with *Mpi* allelic variability in North American mussels (Varvio et al. 1988, McDonald et al. 1991) including native stocks at the two sites used in the present work (Penney & Hart 1999). Genotype-dependent selection at one such locus, *Gpi*, favoring survival of electrophoretically slower alleles has previously been noted in rope-cultured mussels from both Charles Arm and Thwart Island (Penney & Hart 2002a). Based on experimental work showing the enzyme products of different *Gpi* alleles had different thermal optima (Hoffman 1984, Hall 1985), Penney and

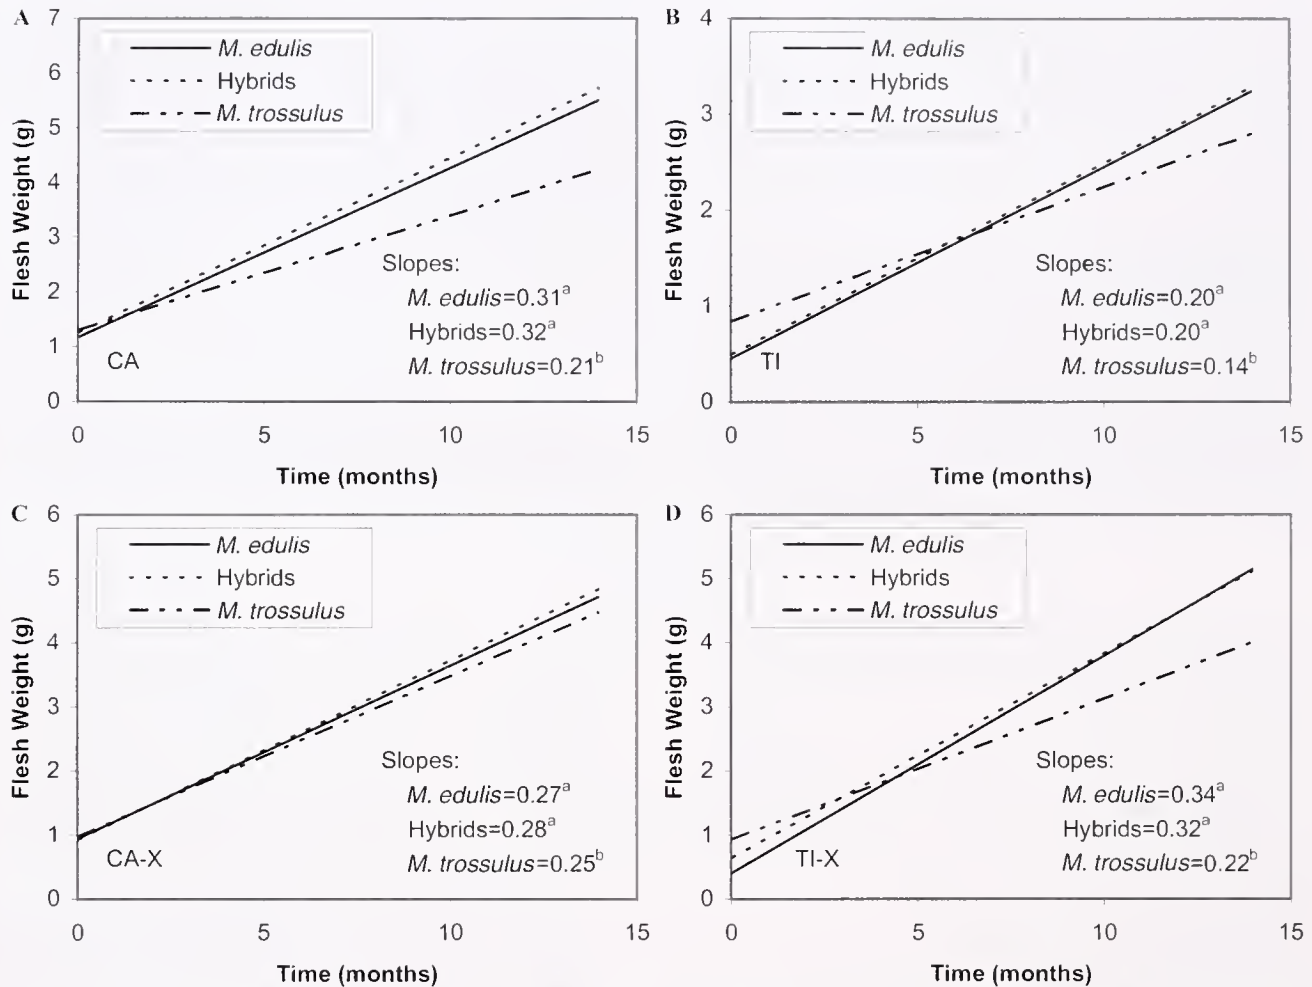

Figure 7. Comparative intrastock growth in flesh weight of *M. edulis*, *M. trossulus*, and their hybrids over the 14 mo growout period for each of the four stock groups. Lines are fitted to the respective linear regression equations of flesh weight over time for each stock group. Different superscripts denote statistical significance between slopes (ANOVA homogeneity of slopes model, $P < 0.05$).

Hart (2002a) advanced the hypothesis that suspended mussel culture may selectively favor individuals with electrophoretically slower *Gpi* alleles, whereas individuals with electrophoretically faster alleles would have an advantage in intertidal shore populations exposed to high air temperatures during emersion.

Electrophoretically slower *Gpi* alleles are associated more with *M. trossulus* than with *M. edulis* (Varvio et al. 1988, McDonald et al. 1991, Penney & Hart 1999), and the incidence of electropho-

retically faster alleles is higher in the native Charles Arm stock than in Thwart Island stock. This could offer a potential physiological explanation for the relatively lower survival of the stocks originating from Charles Arm seed. While purely speculative, the hypothesis that slower *Gpi* electromorphs may be favored in subtidal conditions is indirectly supported by comparison of *Mytilus Gpi* electromorphs with those of the horse mussel, *Modiolus modiolus*. The natural spatial distribution of the latter is subtidal

TABLE 3.

Initial sleeve weight (mean wet weight \times number⁻¹ of sleeve), final mussel biomass after 14 months growout (mean wet weight \times number⁻¹ surviving), and rate of production ((final weight – initial weight)/initial weight) of *M. edulis*, *M. trossulus*, hybrids, and all species combined in each of transferred and non-transferred stock groups. Numbers with letter and numeric superscripts are significant for each variable across rows or down columns respectively (Tukey, $P < 0.05$).

Species	Initial Weight (kg m ⁻¹ sleeve)		Mussel Biomass (kg m ⁻¹ sleeve)				Rate of Production			
	CA & CA-X	TI & TI-X	CA	CA-X	TI	TI-X	CA	CA-TX	TI	TI-X
<i>M. edulis</i>	0.99	0.54	3.15	3.02	2.00	2.74	2.18 ^{a1}	2.05 ^{a1}	2.70 ^{b1}	4.06 ^{c1}
Hybrid	0.21	0.16	0.71	0.88	0.68	0.86	2.41 ^{a1}	3.24 ^{b2}	3.21 ^{b2}	4.31 ^{c1}
<i>M. trossulus</i>	0.11	0.37	0.63	0.36	1.09	0.71	4.64 ^{a2}	2.19 ^{b1}	1.98 ^{b3}	0.93 ^{c2}
All	1.31	1.07	4.49 ^a	4.26 ^a	3.77 ^b	4.31 ^a	2.43 ^a	2.25 ^a	2.53 ^a	3.03 ^b

(Minor 1950) and hence subjected to a colder, relatively narrow range of water temperatures than the typically intertidal distribution of North American mytilid populations. Whether coincidence or not, all 11 electromorphs identified at the *Gpi* locus in Newfoundland populations of *M. modiolus* are electrophoretically slower than those of neighboring mytilids (Penney & Hart 2002b).

In summary, the present work supports the conclusion that the relatively faster rates of weight growth in rope-cultured *M. edulis* and hybrids compared with *M. trossulus* exhibited on their native sites are maintained when transferred to other sites, at least insofar as the donor and recipient sites are not substantially different in environmental conditions. However, the relative survival of the two species and hybrids and hence their relative production performance do not appear predictable based on their *Mpi* genotype alone. This conclusion is consistent with that of Mallet and Carver (1999) who observed that several pure *M. edulis* stocks from Prince Edward Island, New Brunswick and Nova Scotia when

transferred to a site whose native population was primarily *M. trossulus* did not consistently outperform the local mixed-species stock. Therefore, selection of high performance seedstocks appropriate for widespread use by industry remains problematic and a need exists to conduct test transfers of each stock individually or, alternatively, greater understanding of the causal mechanisms of variable survival in mixed-species populations is required. However, because the greater shell weight of *M. edulis* may translate into lower levels of shell breakage during processing (Mallet & Carver 1995), selection of *M. edulis* stocks over local *M. trossulus* or mixed-species stocks for commercial growout appears likely to be a better alternative.

GENETIC MANAGEMENT GUIDELINES FOR CAPTIVE PROPAGATION OF FRESHWATER MUSSELS (UNIONOIDEA)

JESS W. JONES,^{1,2*} ERIC M. HALLERMAN² AND RICHARD J. NEVES^{2,3}

¹US Fish and Wildlife Service, Department of Fisheries and Wildlife Sciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061; ²Department of Fisheries and Wildlife Sciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061; ³US Geological Survey, Virginia Cooperative Fish and Wildlife Research Unit, † Department of Fisheries and Wildlife Sciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT Although the greatest global diversity of freshwater mussels (~300 species) resides in the United States, the superfamily Unionoidea is also the most imperiled taxon of animals in the nation. Thirty-five species are considered extinct, 70 species are listed as endangered or threatened, and approximately 100 more are species of conservation concern. To prevent additional species losses, biologists have developed methods for propagating juvenile mussels for release into the wild to restore or augment populations. Since 1997, mussel propagation facilities in the United States have released over 1 million juveniles of more than a dozen imperiled species, and survival of these juveniles in the wild has been documented. With the expectation of continued growth of these programs, agencies and facilities involved with mussel propagation must seriously consider the genetic implications of releasing captive-reared progeny. We propose 10 guidelines to help maintain the genetic resources of cultured and wild populations. Preservation of genetic diversity will require robust genetic analysis of source populations to define conservation units for valid species, subspecies, and unique populations. Hatchery protocols must be implemented that minimize risks of artificial selection and other genetic hazards affecting adaptive traits of progeny subsequently released to the wild. We advocate a pragmatic, adaptive approach to species recovery that incorporates the principles of conservation genetics into breeding programs, and prioritizes the immediate demographic needs of critically endangered mussel species.

KEY WORDS: freshwater mussels, genetic guidelines, conservation units, artificial propagation, imperiled species.

INTRODUCTION

North America contains the greatest diversity of freshwater mussels in the world, approximately 300 species. However, the superfamily Unionoidea is the most imperiled group of animals in the United States, with 213 species (72%) considered endangered, threatened, or of special concern (Williams et al. 1993, Neves 1999). Already, approximately 35 species, or 12% of the North American mussel fauna, have become extinct in the last 100 y (Neves et al. 1997), an extinction rate comparable to estimated faunal losses in tropical rainforests (Ricciardi & Rasmussen 1999). For example, the Tennessee River basin historically was home to 102 species of mussels, and hence is the putative center of mussel diversity in North America (Parmalee & Bogan 1998). Of those original 102 species, 12 are extinct, 26 are listed as endangered under the Endangered Species Act, 20 are extirpated from the basin, and only about 30 species have stable populations (Parmalee & Bogan 1998). Most of the endangerment is caused by habitat loss and degradation caused by dams, sedimentation, water pollution, dredging and other anthropogenic factors (Neves et al. 1997, Neves 1999). Without immediate efforts to recover the 70 federally listed and numerous other imperiled species in United States watersheds, the extinction of additional species is likely. With this goal in mind, a committee of experts prepared a National Strategy for the Conservation of Native Freshwater Mussels to coordinate a nationwide conservation program (National Native Mussel Conservation Committee, 1998). This document elaborates on the genetic concerns expressed in the national strategy.

Propagation and culture of endangered mussel species typically

is recommended in recovery plans (e.g., US Fish and Wildlife Service (USFWS) 2004), to augment population sizes and to re-introduce species to sites within their historical ranges. A joint policy concerning controlled propagation was adopted by USFWS and the National Marine Fisheries Service (NMFS) to provide guidance and consistency for implementation of species recovery activities involving captive propagation (USFWS and NMFS, 2000). This policy recognizes controlled propagation as a useful tool for establishing new, self-sustaining populations; for supplementing or enhancing wild populations; and for holding offspring of listed species for part of their development if suitable natural conditions do not exist (USFWS and NMFS, 2000). Over the last 10 y, propagation technology has been developed at the Freshwater Mollusk Conservation Center at Virginia Polytechnic Institute and State University (Virginia Tech) and at other facilities in the United States to produce endangered juvenile mussels for this purpose (Neves 2004). Currently, 15 federal and state facilities propagate freshwater mussels in the Southeast and Midwest: Alabama Department of Conservation and Natural Resources, Kentucky Department of Fish and Wildlife Resources, Mammoth Cave National Park (Kentucky), University of Minnesota, North Carolina State University, Ohio State University, Southeast Aquarium Research Institute (Georgia), Southwest Missouri State University (SWMSU), Tennessee Tech University, USFWS Genoa National Fish Hatchery (Wisconsin), USFWS Mammoth Springs National Fish Hatchery (Arkansas), USFWS Warm Springs National Fish Hatchery (Georgia), USFWS White Sulphur Springs National Fish Hatchery (West Virginia), Virginia Department of Game and Inland Fisheries, and Virginia Tech University. These facilities have conducted critical life history studies on freshwater mussels (e.g., Jones & Neves 2002; Neves 2004) and, during the past several years, have released over 1 million juveniles of more than a dozen endangered species into rivers throughout the eastern United States. Survival of laboratory-reared juveniles 1–3 y of age after

release already has been documented. For example, researchers at SWMSU produced thousands of juvenile Neosho mucket, *Lampsilis rafinesqueana* (Frierson, 1927), and reintroduced them in 2000 into historical habitat in the Fall and Verdigris rivers, Kansas. Biologists recovered 28 juveniles of this species at release sites in 2002 (C. Barnhart, SWMU, pers. comm. 2003). The endangered Higgin's-eye pearl mussel, *Lampsilis higginsii* (I. Lea 1857), and endangered oyster mussel, *Epioblasma capsaeformis* (I. Lea, 1834), have been propagated, outplanted, and recovered at release sites in the upper Mississippi River, Wisconsin, and Clinch River, Tennessee, respectively (R. Gordon, USFWS, Genoa National Fish Hatchery, pers. comm. 2002, Jones & Neves, unpubl. data, 2004). Therefore, propagation of mussels offers state and federal hatcheries an opportunity to expand their mission and assume an important role in conservation of biological diversity in the United States.

Federal and state biologists are optimistic about using propagation technology as a recovery tool for endangered mussels, and as mitigation for mussel populations killed by toxic spills or other anthropogenic impacts. However, as these programs mature and become more successful, the genetic implications of releasing captive-reared progeny to natal or other rivers must be considered. Propagation programs will be challenged to increase population sizes, whereas simultaneously trying to avoid negative consequences of altering the genetic resources of populations (Miller & Kapuscinski 2003). Because little is known about conservation genetics of mussels, researchers and natural resource managers will have to apply the science developed by professionals involved in conservation genetics of fishes, marine bivalves, and other organisms (Lannan 1980a, Lannan 1980b, Meffe 1986, Gaffney et al. 1993, Waples 1999, Hallerman 2003).

In this paper, we discuss application of the principles of conservation genetics to protect genetic resources of mussel populations. Our intent is to identify and justify basic, practical, genetic guidelines for their captive propagation. Readers should be aware that the current state-of-knowledge concerning mussel propagation technology is still in its infancy. Hence, some of the population genetic concerns presented are based upon theoretical principles. Key biological information often is lacking for mussels (e.g., population genetic structure, degree and distribution of adaptive genetic variation, numbers of juveniles needed to demographically boost and effectively restore populations, robust estimates of juvenile mortality in the laboratory and field, and effective and minimal viable population sizes). Therefore, questions concerning effects of artificial propagation technology on variation of adaptive genetic traits (e.g., life history traits) are yet unanswered. Propagation programs must take an adaptive approach to management of mussel resources, one that readily learns from results and applies best available science to conservation goals. Ten guidelines are discussed in this paper and are primarily aimed at avoiding genetic hazards associated with implementation of hatchery supplementation programs (Table 1). The intent of this paper is to remind mussel culturists of basic genetic guidelines and protocols to help protect genetic resources of propagated mussel species. We anticipate that as propagation technology advances, more sophisticated genetic management guidelines and plans will be needed to advise hatchery managers.

Life History of Freshwater Mussels

Development of conservation strategies unique to mussels must be grounded in an understanding of their life histories, population

genetic structure and population dynamics. Mussels are suspension-feeders that live most of their lives embedded in the gravel, sand or mud substrates in rivers or lakes. They are generally long-lived animals that exhibit slow to moderate population recruitment rates. Many species commonly live for more than 20 y, with some living more than 150 y (Ziuganov et al. 1998). Eggs of female mussels are fertilized internally by sperm released by males into the water and taken in by females during siphoning. The sexes are separate in most species, but some species are hermaphrodites (van der Schalie 1966, 1970). The embryos then develop in the gills of the female until becoming mature parasitic larvae (glochidia). Once the glochidia are mature, the female releases them into the water, where they must attach and encyst on the gills, fins or epidermis of a suitable host fish for metamorphosis to the juvenile stage. Glochidia of most mussel species require specific fish hosts to transform into juveniles and disperse into new habitats. To maximize attachment of glochidia to host fish, some mussel species produce glochidia in packets (conglutinates) or have mantle-tissue modified into the shape of lures that closely resemble prey items (Fig. 1). Female mantle tissue and conglutinates can mimic insect larvae and pupae, leeches, flatworms, and even other fish, all of which seem to attract host fish closer for possible infestation by glochidia (Parmalee & Bogan 1998). Metamorphosis typically requires 2–3 wk, depending on seasonal water temperatures. Once this parasitic transformation is complete, juveniles excyst and drop from the fish host to begin their lives on the bottom of a river or lake. The juvenile must settle into suitable substrate to have a high likelihood of survival.

Basic life history data, estimates of population size, and assessments of population genetic structure are lacking or sparse for many endangered mussel species. However, this information is critical for making sound management decisions during captive propagation of species. Thus, it is imperative that natural resource managers and administrators recognize that meeting many of the guidelines discussed in this paper will require that studies be conducted to assess population size, population genetic structure and life history parameters prior to implementation of propagation activities for some species, especially when multiple populations of a species exist and augmentation is an intended recovery strategy. In the remainder of the paper, we discuss the genetic issues that should be of concern to mussel culturists, each followed by its recommended guideline.

Addressing Causes of Decline and Extinction

The decline of mussel species throughout North America in the 20th century is attributed to degradation of habitat from various factors, including channelization, damming, mining, pollution, residential development, silting of rivers, and more recently, competition with the exotic zebra mussel *Dreissena polymorpha* (Pallas 1771). Dams change the flow, temperature and dissolved oxygen regimes of free-flowing rivers, such that the reproductive cycle of freshwater mussels is disrupted; gametogenesis is inhibited and fish hosts that prefer shallow, free-flowing river habitat are extirpated from impounded reaches. Thus, dams prevent or inhibit dispersal of mussels, limiting their ability to recolonize historic habitats and sustain natal ranges. Pollution and siltation of rivers degrades benthic habitats and interferes with osmoregulation, feeding and survival of adults and juveniles. Zebra mussels attach to the shells of native mussels and directly interfere with feeding, respiration and reproduction, causing a decline in physiological condi-

TABLE 1.

Summary and justification for the 10 genetic guidelines recommended in this paper for captive propagation of freshwater mussels.

	Summary	Justification
Guideline 1:	Threats to population persistence should be identified and, when feasible, corrected prior to implementing captive propagation for a species.	Increases availability of suitable habitat for population restoration
Guideline 2:	Each mussel species targeted for recovery using propagation technology should have a recovery plan that defines: (1) necessity of genetic characterization of remaining populations; (2) number of populations to be augmented or reintroduced to effectively recover the species; (3) appropriate locations for release of juvenile mussels; (4) number of juveniles to be released per year at a site; (5) number of gravid females to be collected per year for broodstock and (6) field and laboratory protocols to minimize genetic risks incurred by recovery activities.	Promotes implementation of hatchery activities using approved plans designed to protect genetic resources of populations
Guideline 3:	Collection of gravid female mussels for an augmentation ideally should come from the natal river, or from the closest genetically similar viable population, and that for restoring species into historical river habitat from the closest adjacent river system.	Maintains within- and among-population genetic variation
Guideline 4:	Establish an appropriate number of gravid females to be collected each year for propagation from a small population, as well as protocols to monitor survival and recruitment of artificially propagated juveniles.	Minimizes over-collection of broodstock from small populations
Guideline 5:	Maintain the largest possible genetically effective population size (N_e) of propagated juvenile mussels by collecting an appropriate number of adult females each year to use as broodstock, and when feasible, rotate broodstock periodically.	Maintains within-population genetic variation
Guideline 6:	To avoid declines in population fitness due to outbreeding depression, populations that qualify as evolutionarily significant units (ESUs), subspecies, or closely related species should not be mixed.	Maintains among-population genetic variation
Guideline 7:	Reduce domestication selection during propagation and culture of juvenile mussels by mimicking natural life history processes, such as fish hosts, diet, temperature regimes, and habitat of a targeted species as closely as possible in the hatchery.	Increases progeny fitness and survival when released to the wild
Guideline 8:	Protocols are needed to prevent mixing of species or other management units through inadvertent exchanges of juveniles on laboratory equipment.	Maintains among population genetic variation
Guideline 9:	Release an appropriate number of juvenile mussels from an appropriate number of parents at release sites to maximize effective population size (N_e), and at an early life stage to maximize survival in the wild, and to minimize the effects of domestication selection.	Maintains within population genetic variation and reduces domestication selection
Guideline 10:	Monitoring, evaluation, and database management should be regarded as an integral part of any augmentation or restoration program, followed as appropriate with modification of program goals and operations procedures to promote program effectiveness.	Promotes program effectiveness and adaptive management

tion and eventual death (Haag et al. 1993, Neves 1999). Both habitat degradation and nonindigenous species accelerate native mussel population declines by negatively affecting vital rates, notably reproduction, recruitment, survival and dispersal. Identifying threats to population persistence in species targeted for recovery is an important step in determining the feasibility and necessity of captive propagation. Only when the causes of decline are identified and corrected can conservationists effectively implement augmentations and reintroductions to remedy small population problems (Caughley 1994) and re-establish populations within historical ranges. Hence, propagation programs should be viewed as a re-

covery tool that is integrated within larger ecosystem management programs of habitat protection and restoration. Propagation of endangered mussel species is a supplement rather than a substitute for addressing factors responsible for population declines.

Guideline 1: Threats to population persistence should be identified and, when feasible, corrected prior to implementing captive propagation for a species.

Propagation and Recovery Goals

Because species conservation units are identified by genetic studies, the focus of recovery efforts for some species will shift to

Figure 1. (A & B) Phenotypically variable mantle displays of the wavy-rayed lampmussel *Lampsilis fasciola* mimic prey of predatory fish hosts. (C) Conglutinates of kidneyshell *Ptychobranchius fasciolaris* mimic the larval stage of blackflies (Simuliidae) to attract darter hosts, and (D) Conglutinates of fluted kidneyshell *Ptychobranchius subtentum* mimic the pupal stage of blackflies (length of conglutinates is 3–5 mm). Photographs by Jess Jones.

implementation of a captive propagation program. Hatcheries will be used to produce and release sufficient numbers of juvenile mussels of suitable physiological and genetic quality to alleviate the immediate threat of extinction for an endangered mussel species, and to demographically boost a population to the point where it is self-sustaining. Species should be prioritized for recovery based on their risk of extinction using analytic tools such as population viability analysis (PVA) (Beissinger & McCullough 2002). Accomplishing these goals will require restoration, augmentation and protection of viable populations of targeted species and their habitats, and continued research into their life history and population dynamics. *Restoration* is the re-establishment of populations into historical habitats from which the species has been extirpated, whereas *augmentation* is the rehabilitation of demographically depressed populations with translocated adults or hatchery-reared progeny. To achieve these goals, propagation programs will need to adopt straightforward guidelines to help protect genetic resources of species prior to initiating captive propagation activities.

Criteria for down-listing endangered species to threatened and ultimately to recovered status are stated in federal recovery plans (e.g., USFWS 1984, 2004) and are useful for developing propagation goals. These plans provide basic biological information pertinent to the recovery of a species. In addition to biological requirements, recovery plans typically require the existence of 3–6

(e.g., 6 for *Epioblasma capsaeformis*), and sometimes more, distinct viable populations of a species for down-listing from endangered to threatened (USFWS, 2004). Plans define a viable population as a wild, naturally reproducing population that is large enough to maintain sufficient genetic variation to enable the species to adapt and respond to natural habitat changes without further intervention (USFWS 2004). Populations are considered distinct when they are sufficiently separated such that a single mortality event would not eliminate or reduce more than one population.

Guideline 2: Each mussel species targeted for recovery using propagation technology should have a recovery plan that defines: (1) necessity of genetic characterization of remaining populations; (2) number of populations to be augmented or reintroduced to effectively recover the species; (3) appropriate locations for release of juvenile mussels; (4) number of juveniles to be released per year at each site; (5) number of gravid females to be collected per year for broodstock and (6) field and laboratory protocols to minimize genetic risks incurred by recovery activities.

Genetic Hazards and Risks

Hatchery and field activities associated with captive propagation programs pose genetic hazards for a targeted population. A hazard is an adverse genetic consequence of hatchery activities on

a population, and a risk is the probability that a hazard will occur (Busack & Currans 1995). Four types of genetic hazards have been identified: (1) extinction; (2) loss of within-population genetic variation; (3) loss of between-population genetic variation and (4) domestication selection (Busack & Currans 1995). The risk is generally low for causing the extinction of a species (Type 1 Hazard) by recovery activities of a hatchery program; however, the over-collection of broodstock warrants further consideration, to be discussed in the next section. The loss of within-population genetic variation (Type 2 Hazard) is generally caused by propagation of progeny from a limited number of parental broodstock. Loss of within-population genetic variation is accelerated when only a few adults are used as broodstock to produce progeny for release back into the natal population or when there is high variance of reproductive success among breeders (Hallerman 2003). The loss of between-population variation (Type 3 Hazard) is caused when genetic distinctiveness is reduced or lost because of mixing populations that otherwise would not interbreed naturally through migration. Because scientists are still uncertain of the effects of losing genetic variation on mussel population fitness, cognizant hatchery personnel should attempt to minimize human-caused losses of genetic variation (Hard 1995, Waples 1999). Domestication selection (Type 4 Hazard) is the consequence of any change in the selection regimen experienced by a cultured population, relative to what it would have experienced in the wild (Waples 1999). Hatcheries can alter selection regimes in several ways (discussed in detail later). Therefore, personnel involved with the design and implementation of hatchery supplementation programs need to recognize genetic hazards and understand how to avoid or minimize risks associated with propagation activities of targeted species, as discussed in the sections that follow.

Selection of Broodstock Source Populations

Gravid female mussels typically are collected directly from their natal river for use as hatchery broodstock. Populations in close proximity to one another within a river basin are typically best suited for use as broodstock to restore or augment adjacent populations with propagated juveniles. Hence when possible, collection of gravid females for augmenting a population should come from the natal river. Restoration of a species into an historical stream of occurrence should use broodstock from the closest adjacent watershed based on stream distance and with the most similar genetic and ecological characteristics. Source populations should be similar to the recipient population based on: (1) genetic lineage; (2) life history patterns; (3) ecology of the originating environment and (4) physiographic division (Miller & Kapuscinski 2003). In regards to the last factor, the close proximity of populations does not preclude the need for genetic analysis, especially for mussel species that have limited dispersal capabilities and occur in smaller headwater streams, such as some *Epioblasma* and *Pleurobema* spp. that use darters and minnows as hosts. Fine-scale geographic patterns of genetic variation may exist for these species. In such cases, the desire to preserve native population genetic structure (to avoid Type 3 Hazard) must be carefully balanced with the need to augment the population with progeny from a population in another stream. Further, viable populations of many endangered species are few, and some species are reduced to a single population. In these cases, the need for among-population genetic analysis will be limited or not necessary, and selection of source populations for translocation or captive propagation generally can be based on geography alone or criteria to prevent extinction.

Guideline 3: Collection of gravid female mussels for an augmentation ideally should come from the natal river, or from the closest genetically similar viable population, for restoring species into an historical river, from the closest adjacent river system.

Collection of an excessive number of adult female mussels for broodstock from a population can effectively "mine" natural populations by removing reproductive individuals from their source population and potentially contribute to decline (Type 1 Hazard, Miller & Kapuscinski 2003). This can happen when the survival of hatchery-reared progeny is less than survival of those produced naturally. For critically endangered species comprised of a single small population, it may be necessary to establish a maximum number of females to be collected each year for use as broodstock. This practice can help prevent over-collection of gravid females from a population and allow for some level of annual *in situ* reproduction to occur. For example, the population of endangered tan riffleshell *Epioblasma florentina walkeri* (Wilson & Clark 1914) in the Clinch River watershed occurs only in a 1,200 m reach of a tributary stream. The population size has been estimated at $n = 2,000$ (Rogers et al. 2001). However, based on field observations of the number of gravid females releasing glochidia each year in the spring (J. Jones, unpublished data), the actual number of breeding females is much smaller. In such cases, establishing an appropriate number of gravid females to be collected each year for broodstock from a small population is a prudent measure to ensure continuation of annual *in situ* population reproduction. In addition, it is important to monitor the success of propagation efforts, to determine whether recruitment of hatchery-reared juveniles exceeds that of naturally produced juveniles, and that artificial propagation truly contributes to an increase of the targeted population.

Guideline 4: Establish an appropriate number of gravid females to be collected each year for propagation from a small population as well as protocols to monitor survival and recruitment of artificially propagated juveniles.

Maintaining Genetic Resources of Cultured Mussel Species

The American conservationist Aldo Leopold (1949) once stated that the art of successful tinkering requires that we first save all of the parts. Leopold's advice certainly is applicable to conservation of genetic resources of propagated species; however, heeding this advice will require that culturists have detailed knowledge of the genetic composition of populations and an understanding of the effective population size (N_e) needed to maintain appropriate levels of genetic diversity. Genetic studies will be needed to elucidate the genetic structure of populations, especially to determine the presence and proportions of rare alleles in populations. Once this information is available, an appropriate broodstock effective population size (N_e) can be determined to maintain genetic variation.

The effective population size (N_e) is defined as: the size of an *idealized population* that would lose genetic diversity at the same rate as the actual population under consideration (Kimura 1983). An idealized population assumes: (1) no migration; (2) distinct, nonoverlapping generations; (3) number of breeding adults is the same in all generations and (4) all individuals are potential breeders (Kimura 1983). Furthermore, it is assumed that all individuals in an idealized population randomly mate, and the population is closed in all succeeding generations; other simplifying conditions exist as well for an idealized population. Obviously, riverine populations of mussels do not meet these conditions, but the behavior

of how genes are transmitted from generation to generation in an idealized population provides useful theoretical predictions about how real populations can lose genetic diversity. For example, if a real population loses genetic diversity at the same rate as an idealized population of 100, then the N_e of the real population is 100, even if it contains 1,000 individuals (Frankham et al. 2002). For many wild populations, the estimated ratio of effective population size to census population size (N_e/N_c) is approximately 10% (Frankham et al. 2002). Hence, the actual number of breeding adults in a natural or captive population contributing their offspring to the next generation is considerably less than the census size of a wild or broodstock population.

Populations of imperiled mussel species often are small and susceptible to loss of genetic variation through ecological, demographic and anthropogenic factors, to include artificial propagation. Furthermore, once these populations become small, genetic variation typically is further eroded by nonselective forces, such as inbreeding and genetic drift. Random genetic drift occurs at a rate inversely proportional to the genetically effective population size (N_e) (Kimura & Crow 1963). Importantly, loss of within-population genetic variation (Type 2 Hazard) can result in a reduced capacity of populations to adapt to changing environments, which is manifested as a decrease in fitness of individuals within a population (Meffe 1986). Because management for a large N_e is necessary to avoid inbreeding and loss of genetic variation, what, then, are guidelines that mussel culturists and biologists can follow to accomplish these goals? Popular management guidelines—such as the “50/500 rule,” which recommends an N_e of 50 to prevent inbreeding depression and 500 to prevent long-term erosion of genetic variability by genetic drift (Frankel & Soule 1981)—are helpful but often impractical for critically endangered mussel species. Therefore, a long-term strategy is needed to increase N_e over many year-classes, especially for small populations. In addition, because little is known of mussel reproductive biology (i.e., fertilization success rates) equal sex ratios may have to be assumed. For example, if 10 gravid females are collected as broodstock, it might be assumed that each female was fertilized by one male, and therefore, $N_e = 20$. However, it is likely that N_e is much lower in natural populations of some species because of hermaphroditic reproduction and low fertilization success between males and females. A target sample of 20–25 randomly collected animals can contain ~98% of the expected heterozygosity of a wild population (Lacy 1994), and could be achieved for even small populations over 1–5 y. Accordingly, multiple gravid female mussels should be collected annually from various sites to represent a range of river locations, habitats and subpopulations within the source population. Larger ($n > 5,000$) populations of an endangered mussel species are likely to contain considerably higher amounts of genetic variation; therefore, collection of a greater number of gravid females per year is necessary to increase N_e and genetic diversity of propagated cohorts over time. Other researchers have recommended collecting a minimum of 50–200 individuals to serve as broodstock (Ryman & Stahl 1980, Allendorf & Ryman 1987). Such a strategy helps ensure that any rare alleles (e.g., those at a frequency of <5%) occurring in a population are adequately represented in the broodstock and subsequent progeny. Thus, for larger populations where collection of gravid females can easily be accomplished, it is recommended that >50 individuals be targeted over time to augment or re-establish populations. All females should be tagged prior to their release back to the river or if held in a hatchery as captive broodstock. This will prevent excessive

use and over-representation of the genomes of a limited number of females (see discussion of Ryman & Laikre [1991] effect below). In addition, tagged mussels can be tracked in the field and hatchery for survival and subsequent gravidity. In the future, factorial mating designs (in which males and/or females are mated with multiple members of the other sex) might be used to increase genetically effective population size of hatchery-produced progeny. Thus, with time, we hope to gain the ability to implement direct matings and thereby minimize loss of within-population variation.

Guideline 5: Maintain the largest possible genetically effective population size (N_e) of propagated juvenile mussels by collecting an appropriate number of adult females each year to use as broodstock and, when feasible, rotate broodstock periodically.

Because the effect of loss of genetic diversity in mussel populations is unknown, management of effective population size and genetic variation for mussel species should be a primary concern to biologists and culturists. However, technical constraints confronting propagation of some endangered mussel species dictate that these genetic concerns will be difficult to accommodate initially. Some species are now sufficiently rare, that obtaining even a few gravid females per year for propagation is difficult (Rogers et al. 2001, Jones et al. 2004). The high fecundity and output of glochidia by individual females provides an opportunity to produce many more juveniles than would have survived in nature; such recovery opportunities should be exploited to alleviate demographic and environmental threats to persistence of small populations. Thus, in the initial stages of recovery for some endangered mussel species, increasing population density to alleviate immediate threats to population persistence will have to be weighed against managing for increasing genetically effective population size and genetic diversity. Clearly, there is a need to balance our capacity to produce and release numerous progeny while trying to maintain genetic diversity of populations (Type 2 and 3 Hazards).

Outbreeding Depression

Outbreeding depression is a decrease in fitness of progeny upon breakup of coadapted gene complexes resulting from mating of distantly related individuals (Dobzhansky 1937). Although untested in freshwater mussels, outbreeding depression has posed a threat to population viability in some species of marine bivalve mollusks (Lannan 1980a, Lannan 1980b, Gaffney et al. 1993, Boudry et al. 2002). We hypothesize that mussel species and populations that have limited dispersal capabilities and that are subject to local environmental selection pressures may have developed coadapted gene complexes for adaptation to such environments, to include local host fish communities. For example, recent research on fish host specificity has demonstrated that glochidia obtained from allopatric mussel populations can exhibit significant among-population variation in transformation success when exposed to local fish host communities (Rogers et al. 2001, Eckert 2003, Jones et al. 2006). Other factors, such as differences in various life history parameters (e.g., spawning seasonality), population demographic parameters, physiological response to water quality (e.g., differences in local geochemistry) and other potentially adaptive traits should be assessed by biologists. Thus, we suspect that some populations of freshwater mussels may be vulnerable to outbreeding depression, and mixing distinct populations may disrupt genetic adaptation to local environmental conditions.

Guideline 6: To avoid declines in population fitness caused by outbreeding depression, allopatric populations that qualify as evo-

lutionarily significant units (ESUs), subspecies, or closely related species should not be mixed.

Domestication Selection

Domestication selection (Type 4 Hazard) causes genetic changes in captive-held populations. In the captive rearing environment, artificial selective forces can replace those of natural selection. Domestication selection occurs because a different set of progeny survive in the hatchery than would have survived in the wild. Genetic changes can affect morphological, physiological, or behavioral traits and lead to decreased performance and survival of captive-reared progeny in natural environments. Because mussel propagation is still in its infancy, domestication selection has not been documented in the rearing of a mussel species; however, it has in the rearing of fishes (Miller & Kapuscinski 2003) and marine bivalves in hatcheries (see annotated bibliography by Moore & Seeb 2001). For example, many salmon hatcheries producing fish to augment wild populations are careful to collect breeders from different time-periods through the spawning run of a particular stock. This field-collection practice allows genetic representation of breeders that collectively spawn from early to late in the run. Similar practices may be necessary for some species of mussels to prevent artificial selection. For example, females of the endangered oyster mussel *Epioblasma capsaeformis* in the Clinch River, Tennessee, typically begin displaying their mantle-pad lure and releasing glochidia to host fish in April and continue into June (Jones et al. 2005). Some individual females display early in the spring, whereas others display much later. These differences in the timing of release of glochidia by *E. capsaeformis* may be genetically controlled and suggest that gravid females should be collected at different times throughout the glochidial release period. If, for example, time of glochidial release is under genetic control, then excessive propagation and release of juvenile mussels from females collected in the early spring could shift forward the glochidial release period of a targeted population relative to that of the wild population.

Research is needed to determine how domestication selection could alter the genetics of captive-reared juvenile mussels through stages in the propagation process, including investigation of the following: (1) most appropriate time of year to remove glochidia from the female mussel to maximize maturity of glochidia (Jones et al. 2005); (2) use of marginally-suited host fish for transforming glochidia to the juvenile stage; (3) appropriate diet, optimum substratum, exposure to disease and rearing temperatures and (4) length of culture period in captivity before release to the wild. To minimize domestication selection, we must clearly understand natural regimes and requirements for fish host usage, grow-out temperature, substrates, growth rates, light regimen, diet and size of juveniles at release relative to naturally-produced juveniles, thereby mimicking the ecology and habitat of a species as closely as possible throughout the propagation process (Maynard et al. 1995, Flagg & Nash 1999).

Guideline 7: Reduce domestication selection during propagation and culture of juvenile mussels by mimicking natural life history processes, such as fish hosts, diet, temperature regimes, and habitat of a targeted species as closely as possible in the hatchery.

Laboratory Protocols to Prevent Mixing of Mussel Species

The establishment of laboratory protocols to prevent the inadvertent mixing of species or other management units is important

to protect the integrity of genetic resources. Most propagation facilities rearing juvenile mussels for augmentation or restoration are cultivating multiple species and populations from different drainages. For example, at the Freshwater Mollusk Conservation Center at Virginia Tech University, juveniles of 6–9 endangered mussel species are produced each year, representing species from several major river drainages. In these situations, separate tank systems are required for holding host fish and for grow-out of juveniles from different drainages. Because juvenile mussels are small (~200–1,000 μm) for the first 60 days of life and can easily attach to laboratory equipment used for handling juveniles, such as sieves, siphons and Petri dishes, these items also should be kept separate for each lot and disinfected regularly. All hatchery personnel should be trained in field and laboratory protocols to reduce the risk of unintentional mixing of cultured populations.

Guideline 8: Protocols to prevent mixing of species or other management units through inadvertent exchanges of juveniles on laboratory equipment are needed to protect genetic resources of freshwater mussel populations.

Release of Propagated Juveniles

A suite of factors should be considered before juvenile mussels are released to the wild. Such planning is especially important for critically endangered populations with small effective population sizes (N_e). Small populations (e.g., $n = 500$ –1,000 and $N_e < 50$ –100) warrant special attention if they serve as a source for augmentation or reintroduction. First, production and release of thousands of juveniles from a small number of adult females into a small ($n < 1,000$) recipient population can significantly decrease N_e , because of unequal contributions of progeny from only a few progenitors (Ryman & Laikre 1991). Therefore, a target number of offspring should be established for release into a small population prior to augmentation. Excess progeny could be released at adjacent shoals or at other acceptable sites. Second, selection of suitable release sites should be based on at least the following criteria: (1) biological requirements of the species, such as presence of fish hosts; (2) habitat quality and (3) thorough assessment of localized and upstream threats to release sites. Third, juveniles should be released at the earliest life-stage possible that will maximize survival in the wild. There is a trade-off between how long juveniles are reared in the hatchery, to increase survival rate relative to juveniles reared naturally and continued exposure to the hatchery environment and the associated extent of domestication selection (Miller & Kapuscinski 2003). Exposure to natural environmental patterns and selective forces at an early life stage may prove most beneficial to ensure fitness in the wild of hatchery-reared juveniles. Fourth, juveniles should be released under moderate-to-low flow conditions to allow settlement at the selected site on the river bottom, and at the appropriate time of year (spring-summer). Fifth, release methods and sites should be selected to increase the range and connectivity of localized demes and populations. For example, juveniles could be released at suitable sites between known locations of upstream and downstream demes. Sixth, as propagation technology improves and juveniles are grown to larger sizes, juveniles should be marked with a tag or chemical stain to facilitate monitoring efforts (see Eads & Layzer 2002).

The possibility of releasing host fish infested with glochidia would allow natural dispersal and colonization of habitats otherwise excluded by only releasing hatchery-reared juveniles, spread risk of mortality at localized stream reaches, and may minimize

future inbreeding. However, this practice risks loss of juveniles after settlement into unfavorable areas, and makes monitoring of survival success difficult. Under some circumstances, such as in small streams, this strategy may be more effective than site specific releases of cultured juveniles.

Guideline 9: Release an appropriate number of juvenile mussels from an appropriate number of parents at release sites to maximize effective population size (N_e), and at an early life stage to maximize survival in the wild, and to minimize the effects of domestication selection.

Monitoring and Adaptive Management

Captive propagation of mussels is a new recovery option, and is as much an art as a well-established science at this time. Success must be measured not in terms of how many juveniles are outplanted, but rather in terms of how many juveniles recruited into or established a spawning population. Furthermore, data on (1) number of gravid females used to produce juveniles; (2) locations where females were collected; (3) number of juveniles released per site and river location; (4) juvenile characteristics (e.g., age, size and condition) and (5) river conditions at the time of release, should be recorded and submitted to the responsible natural resource agency. Standard data sheets should be prepared and used for all releases. It is critical that protocols to monitor survival and recruitment of artificially propagated juveniles are established and implemented, and project data are collected in an appropriate agency database. Ultimately, success will be measured in terms of the establishment of self-sustaining populations. Hence, monitoring should be regarded as an integral part of any captive propagation and release program.

Because of the many unknowns in mussel biology and uncertainties in long-term effects, hatchery programs may be experimental in nature, but should be integrated into an adaptive management program, with careful attention to monitoring and reevaluation of goals and protocols. Under the adaptive management paradigm, results of monitoring are used, as appropriate, to modify management goals and operations procedures so that, over time, learning occurs and the overall program becomes more effective

(Holling 1978). Adaptive management has proven useful for management of Pacific salmonids (Hilborn & Winton 1993, Walters et al. 1993), and we acknowledge that it is essential for captive propagation and outplanting of imperiled mollusks.

Guideline 10: Monitoring, evaluation, and database management should be regarded as an integral part of any augmentation or restoration program, followed as appropriate with modification of program goals and operations procedures to promote program effectiveness.

Concluding Remarks

We advocate application of the principles of conservation genetics to species recovery efforts for freshwater mussels. However, these principles should be recognized as guidelines, and not as goals per se (Neves et al. 1997). Propagation technology and techniques will continue to develop as a recovery tool for a greater suite of species, and to hopefully prevent further extirpations and extinctions. Propagation may effectively alleviate problems associated with small populations, and has the potential to re-establish populations extirpated by known and ameliorated causes. Although propagation offers a wealth of benefits for conservation and restoration, managers of propagation facilities must recognize how each stage in the propagation process can affect the genetic integrity of mussel populations targeted for recovery. A conservation program of sound aquaculture practices, knowledge of the faunal group and application of conservation genetic principles will provide the tools needed to recover and restore species now threatened with extinction.

ACOUSTIC DETERRENTS DO NOT REDUCE BLACK DRUM PREDATION ON OYSTERS

KENNETH M. BROWN,¹* GARY W. PETERSON,² GERALD J. GEORGE¹ AND
MICHAEL MCDONOUGH³

¹Department of Biological Sciences; ²Coastal Fisheries Institute; ³Department of Oceanography and
Coastal Studies Louisiana State University, Baton Rouge, Louisiana 70803

ABSTRACT We studied the effectiveness of acoustic deterrents in limiting predation on Louisiana oyster leases by black drum *Pogonias cromis*. Three acoustic deterrents were used: (1) natural or synthesized alarm sounds; (2) synthesized, low frequency sound played over short time intervals and (3) mechanically produced sound. Fish locations were monitored in all approaches and feeding rates on oysters were recorded in approaches 1 and 3. Experiments in salt-water ponds indicated that alarm calls from males, or synthesized tapes (approach 1) did not depress fish feeding rates or cause fish to avoid transducers, in comparison with controls. Lower frequencies (<20 Hz, approach 2) displaced fish 8 m further from transducers (about 20% of the distance possible) relative to controls. Finally, a solar-powered hammer (approach 3) was designed as a more logistically feasible deterrent. Fish were weakly attracted (although control and experimental locations differed by only 5%). Because acoustic deterrents were either ineffective at displacing fish or lowering feeding rates on oysters, or required considerable electrical power to displace fish, we conclude that they are not practical to control losses of oysters on leases to black drum.

KEY WORDS: black drum, sound deterrents, oysters

INTRODUCTION

The black drum, *Pogonias cromis* (Linnaeus, 1766), is a significant predator of oysters in the northern Gulf of Mexico (Cave 1978, Sutter et al. 1986, Dugas 1986). Mortality rates are low in intertidal oyster beds because of aerial exposure and the aggregated growth form, but commercial, subtidal oyster leases often experience high mortality. Oyster mortality is especially high after small, individual “seed” oysters are bedded in the fall, or when black drum return to estuarine waters in the spring after breeding in coastal passes. In a survey of lease holders in Louisiana (LADWF 2000), 55% reported black drum caused losses to production. With powerful pharyngeal teeth, black drum crush and eat 30 oysters per night, and black drum >70 cm in length can feed on oysters 75 mm in length (Cave 1978). Our earlier work indicated mortality rates as high as 90% on experimental leases, and that scent deterrents (e.g., from dead con-specifics) were not effective (Brown et al., 2003).

Some evidence suggested that acoustic deterrents might be effective. Black drum are vocal (as are other Sciaenid fishes) and emit low frequency “drumming” sounds, which may attract females or act as alarm calls. These sounds can be heard by humans both in air and water and are produced by muscular contractions against an inflated swim bladder that acts as a resonator (Smith 1905). Black drum detect frequencies ranging from <100–800 Hz and are most sensitive to frequencies <500 Hz (Ramcharitar & Popper 2004).

Acoustic cues can also alter fish distributions and feeding rates in other fish. Haymes and Patrick (1986) excluded alewives from water intakes using low-frequency sounds. Ross and Dunning (1996) used 190 dB high frequency (122–128 kHz) broad-based sound, and reduced alewife abundance by 51% at power plant intakes in Lake Ontario. Knudsen et al. (1994) found that salmon (whose hearing range extends from 5–150 Hz), avoid low frequency infra-sound (10 Hz) but not high frequency sounds (150 Hz), and argued that low frequency sounds mimic the swimming

of predators. Maes et al. (2004) used multiple sounds in a frequency range of 20–600 Hz to decrease fish abundance at an estuarine power plant by 60%.

Our research objective was to determine if acoustic deterrents either reduced the feeding rates of black drum on seeded oysters, or caused them to avoid oyster leases. Three general types of acoustic deterrents were used: (1) natural or synthesized alarm sounds; (2) synthesized low frequency sound played over short time intervals and (3) mechanically produced sound. Fish locations were monitored in all approaches and feeding rates on oysters were recorded in approaches 1 and 3.

MATERIALS AND METHODS

Experiments were conducted in four 0.1 ha saltwater ponds at the Lyle St. Amant Marine Laboratory on Grand Terre Island (29.3°N 89.99°W) operated by the Louisiana Department of Wildlife and Fisheries. Ponds contained pumped-in Barataria Bay sea water (over the experimental interval, mean temperature was 23.4 ± 0.6°C [±SE], salinity 20.6 ± 0.4 PSU, and dissolved oxygen 8.3 ± 0.4 mg/L) and had removable stand pipes to aid in draining ponds to recapture fish. However, pumps were not run during experiments to eliminate masking of experimental sounds. The ponds were large enough (25 m × 40 m × 1 m deep) so that sound would attenuate with distance (see later in discussion) and reflections would be minimized, allowing drum to find areas with low sound. Although low frequency sounds attenuate rapidly in shallow water over soft sediments (Rogers & Cox 1988), oyster leases are typically seeded under such conditions, and the ponds thus accurately model similar conditions on oyster leases.

In March 2001, using contiguous 30,000 L concrete raceways at the laboratory, we played back tapes with pure sinusoidal wave forms at various frequencies and observed individual black drum. Frequencies from 10 Hz to 100 Hz caused fish to move to the opposite end of the tank. However, there was considerable “cross-talk” (sound transfer among the concrete tanks) along with standing waves that complicated determining the strength of acoustic signals.

Similar studies however indicated a clear gradient in sound

*Corresponding author. E-mail: kmbrown@lsu.edu

Figure 1. Plot of sound volume detected against distance from the transducer at two frequencies in the experimental ponds.

intensity along the length of the 0.1 ha ponds, similar levels on each side, and little cross talk among ponds (Fig. 1). An Argotech model 210 underwater transducer (positioned at the center of one end of the pond) produced a pure tone of 164 dB μ Pa/@ 1 m at a frequency of 100 or 300 Hz. Sound levels were measured with a "Dolphin Ear" DP100-6 hydrophone (frequency response 7 Hz to 22 KHz) and decibel meter at each corner near the transducer (~12.5 m distant), halfway down each side (~23.5 m), and at the center (~40 m) and each corner (~42 m) of the opposite end. At 100 Hz, transmission loss was approximately 90% at 12.5 m, 97% at 23.5 m, and 99% at 40–42 m. At 300 Hz, loss was 96.4% at 12.5 m, 95% at 23.5 m, and 99.2% at 40–42 m. Little variation in signal strength occurred across the pond at any distance, and signals were not detected in adjacent ponds, indicating no cross talk.

For approach 1, experiments were conducted from January to April 2002. Two Argotech model 210 underwater single-neoprene membrane transducers, at the center of one end of each experimental pond, were powered by a 200 W Peavy CS800X amplifier, connected to a cassette recorder. Two continuous-loop tapes were supplied by Argotech. The first was alarm "drumming" by a male in the raceways, edited to remove splashes, and with bandwidth limited to 4 KHz (frequency peaks were at 37, 70, 146, 210 and 300 Hz, Fig. 2). The second was a synthesized recording predicted to produce avoidance based on previous work by Argotech (Fig. 3, with peaks at 20, 40, 60 and 267 Hz).

Transducers were switched weekly, so treatment ponds were controls and the previous controls were treatments, to minimize pond-specific differences in fish feeding rates or habituation. After four weeks, the sound was changed to the synthesized tape (and all fish replaced) and another four, weeklong experiments were run in the same pattern.

Each pond had 5 black drum, with a mean total length of 82.4 ± 1.6 cm (SE) and weight of 9.9 ± 0.4 Kg. Fish were collected by trot line or rod and reel in nearby (<2 Km) Barataria Pass, and were held in raceways. Five fish were used to facilitate tracking (see below). Actual school size has yet to be studied in Black Drum, but we have observed them in both small (~5) and larger groups in Barataria Bay (K. Brown, pers. obs.).

To study feeding, 50 oysters of vulnerable size (50–150 g total wet weight, 5–10 cm shell length, Brown et al. 2003) were placed in each of six Nestier trays (0.67 m² bottom area mesh trays with 0.1 m high walls). Three trays were along the short edge of each pond, with the transducer at the center of the trays on one end. No other food was provided. Experiments lasted three days; oysters were replaced daily to determine feeding rates, and trays were then removed for three days to starve fish before the next experiment.

Figure 2. A frequency domain plot (top) and time domain plot (bottom) of an alarm call recorded from a male black drum in the 30,000 L raceways. Frequency peaks are indicated in the text.

Feeding rates were analyzed in a 1-way analysis of covariance, with time since the start of the experiments as a covariate to control for seasonal effects.

To follow movement, fish were tagged with numbered "spaghetti" tags inserted below the soft dorsal fin and attached to individually colored small (~2 × 7 cm) styrofoam floats by 200 pound test, monofilament line. Because the floats were small, and black drum are relatively large fish, they did not impair movement or grouping patterns. Locations (to the nearest 0.5 m) were recorded hourly from 10:00–16:00 on a grid laid out in the ponds, and distances from the transducer digitized. The hourly mean distance of the five fish from the transducer (or the same location in the control ponds) was analyzed in a 1-way repeated measures analysis of variance, contrasting the controls and two recorded sounds. The repeated measure was hour of day.

The second approach involved broadcasting pure tones at frequencies of 10, 15, 20, 25, 30, 40, 50 and 60 Hz in a single pond. The same amplifier powered a single, larger Argotech model 220

Figure 3. Frequency domain plot of the synthetic tape produced by Argotech and used in approach 1.

twin-neoprene membrane transducer at the center of one end. Although lower-frequency sounds attenuate rapidly in shallow, soft-bottomed environments (see earlier discussion), and we did not explicitly measure attenuation in this experiment, signals carried far enough to displace fish (see results), and were thus apparently audible. Following Maes et al. (2004), we contrasted fish positions during sound-on and sound-off periods. Each experiment had a five-minute interval with sound, and five minutes without. In this experiment, 4 tagged fish were used, and we used similar methods to record the positions of the tagged fish (mean length = 94.7 ± 2.3 cm, mean weight = 13.0 ± 0.9 KG) each minute. The amplifier was then turned off for five minutes before the next frequency was tested. The experiment was repeated the next day, so that 10 replicate observations were recorded for each frequency and its corresponding control period. The locations of the four fish relative to the transducer at each minute interval were analyzed in a 2-way analysis of variance (sound on or off versus frequency). Experiments were conducted from December 6 to 8, 2002.

For the final approach, we collaborated with biological engineers at Louisiana State University's Department of Biological Engineering to produce a mechanical, sound-producing device. The rationale was 2-fold. First, the underwater transducers required considerable power, and were prone to leaks. Second, striking a metal oil drum with a wooden stick near the pond edge caused fish to rapidly move away. The device (Fig. 4) consisted of two 55 gallon, sealed steel drums that provided buoyancy. One drum had an internal electric motor (Fig. 4, inset) activating a spring-loaded hammer. Both the time between impacts and the number of impacts per application were adjusted several times during the experiment by a dial on the top of the apparatus to limit habituation. The motor was powered by a 12-V automotive battery charged by a solar cell suspended above the drums.

The experiment was conducted in one experimental and one control pond. Four tagged fish (mean length = 86.4 ± 1.8 cm, mean weight = 10.3 ± 0.5 KG) were used in this final experiment in each pond. The apparatus could not be easily transferred among ponds, so experimental and control ponds were not reversed. Each experiment lasted two days. On the first evening, six trays filled with 50 oysters were added, and tagged fish locations determined

for six hours the next day. In earlier experiments, hourly locations were a "snapshot", as fish moved constantly. We therefore noted average fish locations for the first 10 minutes of each hour in this experiment. A repeated measures analysis of variance indicated no repeated measures effect ($P = 0.15$), so all 60 observations ($6 \text{ h} \times 10 \text{ observations}$) were used as replicates in a 1-way analysis of covariance. The experiment was repeated five times during April to May 2003. Number of days since the start of the first experiment was the covariate.

RESULTS

For the initial approach, feeding rates were not depressed by alarm sounds ($F_{2,59} = 0.7$, $P = 0.52$), in comparison with the synthetic sounds or the control (Fig. 5). On average, fish exposed to alarm sounds consumed 49% of the oysters provided daily, in comparison with 67% with synthetic tapes, and 61% in controls. The covariate was significant ($F_{1,59} = 22.6$, $P < 0.0001$) because feeding increased with warmer temperatures or acclimation of fish.

Hour of observation did not affect fish location (Wilk's $\lambda = 0.83$, $F_{6,46} = 1.5$, $P = 0.19$), nor was there a treatment effect ($F_{2,51} = 0.4$, $P = 0.7$). There was an interaction (Wilk's $\lambda = 0.63$, $F_{12,92} = 2.0$, $P = 0.04$), although inspection of the pattern of treatments across hours (Fig. 6) revealed no obvious trends.

In the second approach with lower-frequency sound, frequency was not significant ($F_{8,152} = 0.7$, $P = 0.69$), but there was a difference in location between when the transducer was on and off ($F_{1,152} = 116.6$, $P < 0.0001$), and an interaction between frequency and sound activation ($F_{8,152} = 5.7$, $P < 0.0001$).

Figure 5. Mean feeding rates on oysters (\pm SE) from the initial transducer experiment (approach 1). Drum = average for alarm sound, Synthetic = average for synthesized sound, and Control = average without sound.

Figure 4. Solar-powered, sound producing mechanism. (A) Automotive battery powering electric motor, (B) Solar cell charging automotive battery, (C) Sealed 55 gallon harrel, (D) inside barrel showing electric motor and hammer.

Figure 6. Average locations (distance from transducer, \pm SE) of fish in the initial transducer experiment, as a function of treatment and hour of the day.

Fish averaged 17 m from the transducer when it was inactive, versus 25.1 m when it was broadcasting. For example, at 15 Hz (Fig. 7), fish moved from less than 10 m to over 33 m away from the transducer within 3 min. and returned to within 15 m after the transducer was switched off. The small standard errors in the figure reflect the close spatial clustering of the fish. The interaction occurred because experimental and control fish locations converged at frequencies >20 Hz (Fig. 8). Comparisons of locations with Tukey *a posteriori* tests indicated fish were further away from transducers at 20 Hz, and closer at 50 Hz, with the distances in all other treatments overlapping. However, eight of the nine highest displacements occurred when the transducer was on, again suggesting the fish were avoiding the lower frequency sounds.

For the final approach with the mechanical device, there was a difference in fish location between the experimental and control ponds ($F_{1,596} = 8.5$, $P < 0.01$). However, the trend was opposite of that predicted, with fish on average 19.2 m away in the control pond, versus 17 m in the experimental pond (Fig. 9). There was also a difference in feeding rates ($F_{1,18} = 24.6$, $P < 0.0001$) with rates in the control pond only 2% of those in the experimental pond (Fig. 9). The covariate did not have a significant effect ($F_{1,19} = 0.7$, $P = 0.42$).

DISCUSSION

The first approach suggested that there was little effect of male alarm sounds either in depressing feeding, or in displacing

Figure 7. Distance of fish (\pm SE) from the transducer in the 15 Hz experiment (approach 2). The Box represents the period when the signal was switched on.

Figure 8. Distance of fish from the transducer (\pm SE) versus sound frequency. Experimental = sound on, Control = sound off.

black drum from the sound source. Although there were no significant main effects on fish location, variation among the treatments at different times of day caused a significant statistical interaction.

The second approach did indicate displacement of fish from the transducer over the short term at lower frequencies. However, the electrical power necessary to propagate these low frequency sounds underwater makes this approach logistically impractical as a deterrent in field applications (see discussion below). Underwater transducers were also prone to leaks and malfunctions, and had to be replaced on several occasions by Argotech during the experiments.

The results of the first two approaches must be interpreted carefully. Again, low frequency sound attenuates rapidly in shallow, soft-bottomed environments (Rogers & Cox 1988), possibly limiting fish responses. However, the initially measured sound field, although indicating considerable signal loss across the pond, also indicated a sound volume at the opposite end that was still above the threshold of black drum at 100 Hz, about 90 dB re $1 \mu\text{Pa}$ (Ramcharitar & Popper 2004). Second, fish were evidently able to

Figure 9. Displacement of fish from the sound-producing device (sound), and feeding rates, in comparison with fish in the control pond (control). Values are means \pm SE. Dist = distance from device, left axis; Feed = oysters consumed, right axis.

hear the low frequency sounds, because they were displaced. Finally, regardless of the mechanism (whether fish ignored the sounds or could not discern them), the first two approaches were either not effective (approach 1) or practical (approach 2), negating their use in management. We are confident similar results would occur on oyster leases, because the ponds again had similar depth and sediment type.

The last approach, a solar-powered hammer, was more cost effective but weakly attracted fish. However, the average distances differed by only 2 m, only 5% of the distance available. The higher feeding rates in the experimental pond must also be interpreted carefully, because the apparatus could not be moved between ponds. The experimental fish may have been more accustomed to feeding on oysters, similar to differences in feeding between individual groups of fish used in past experiments (Brown et al. 2003).

We conclude that the acoustic deterrents used in approach one and three were not effective for reducing predation by black drum, or could even attract fish. Using sound stimuli at low frequencies

to displace fish (approach 2), although effective, requires more power, and we conclude costs to lease holders would outweigh benefits. Many Louisiana oyster leases are in remote areas, and supplying sufficient electrical power is again problematic. Conducting these lower frequency experiments over longer time intervals might also have revealed habituation in the responses.

ACKNOWLEDGMENTS

This research was funded by Sea Grant's Gulf Oyster Initiative Program (GOIP - 19). The Louisiana Department of Wildlife and Fisheries and the Lyle St. Amant Marine Laboratory provided experimental raceways and saltwater ponds, and also provided lodging and a logistical base. Mr. P. Vujnovich Jr. provided oysters used in feeding experiments in the ponds. Professor Randy Price, LSU Department of Biological Engineering, designed and constructed the solar-powered device. Argotech provided transducers, amplifiers and technician support during the initial experiments.

ABSTRACT The European oyster (*Ostrea edulis*) was introduced to the Nova Scotia aquaculture industry 30 years ago using stocks imported from naturalized populations in Maine whose ancestors originated in the Netherlands. This study used 5 microsatellites to assess the level of genetic diversity in several hatchery stocks and naturalized populations from Nova Scotia, New Brunswick, British Columbia and Maine. Some genetic erosion was shown to have occurred in the Maritimes populations, with the largest loss of alleles being experienced by the hatchery stocks. In spite of this loss, genetic diversity and heterozygosity in the Maritimes populations are still relatively high. Relationships within and between the populations and the existence of kin groups within the collections were overall consistent with our knowledge of the historical transfers of oysters between different locations. Furthermore, the established database allowed to assign with good confidence unknown oyster samples to their geographic origin. This would be a useful forensics tool in the case of an illegal transfer from a diseased area.

KEY WORDS: *Ostrea edulis*, European oyster, flat oyster, microsatellites, Maine, genetic diversity

INTRODUCTION

European oysters (*Ostrea edulis*) were introduced to Nova Scotia 30 years ago, principally from naturalized Maine populations whose ancestors originated in the Netherlands in 1949 (Loosanoff 1955, Welsh 1964, Newkirk et al. 1995). They were brought to Nova Scotia to develop oyster aquaculture in the cool, high salinity areas on the Atlantic coast of the province. These waters are generally too cold in the summer to ensure reproductive success of the native American oyster *Crassostrea virginica*, which subsists in only a few small isolated populations in estuaries and tidal lakes (Spares & Dadswell 2001). Growing conditions for *O. edulis* are good in the waters off the Atlantic coast of Nova Scotia but spawning conditions are only marginal in most sites. In addition, the summer season is relatively short, yet good spat growth is essential for ensuring subsequent winter survival. However in a few locations, European oysters have managed to naturalize and have established apparently sustainable populations. Nevertheless, the development of the European oyster industry in Nova Scotia over the past 30 years has relied exclusively on hatchery produced spat that are transferred to grow-out sites at the end of summer/beginning of fall.

There are now separate groups of European oysters in Nova Scotia that may be genetically differentiated to various degrees because of human and environmental influences (e.g., severe winter mortalities in 1990/91 and in 1991/92 or bottlenecks in hatcheries). In addition, the parasite *Bonamia ostreae* is known to be endemic in the European oyster population of Maine but is not present in Nova Scotia. This disease devastated the French oyster industry in 1979 and could have similar devastating consequences if introduced to Nova Scotia, one of the last places in the world where this disease has not been reported. Any importation of new oysters from Maine or other sources is consequently prohibited for this reason.

The preservation and utilization of genetic variability in any broodstock program is a critical and complex issue. Numerous studies have shown that genetic variations can be lost at a rapid rate in hatcheries leading to inbreeding increase and depression (e.g., Beattie et al. 1987, Hedgecock & Sly 1990, Naciri-Graven et al. 2000, see review in Herbinger et al. 2003). In 2001, larvae and spat started to experience massive mortalities in Nova Scotia's hatcheries. Water quality, such as variation in temperature or organic/bacterial load, was suspected to be responsible for the problems, but the possibility of genetic erosion and concomitant increase in inbreeding, coupled with the inability to import new genetic material to Nova Scotia, was also a serious concern. This study was thus concerned with characterizing the present level of genetic variability observed in hatchery and naturalized stocks, the latter being a potential source of *Bonamia*-free broodstock to counteract potential serious losses of diversity in the former. The existing genetic variability and differentiation of various groups of naturalized populations and hatchery stocks of oysters in Nova Scotia was assessed using five microsatellite DNA markers, in comparison with hatchery or endemic *O. edulis* populations in other parts of Canada, Maine and Europe. This study also used DNA marker based pedigree reconstruction to detect the presence of related individuals among any of the groups, as evidence of on-going genetic bottleneck, and it evaluated whether the same microsatellite DNA information could be used to detect illegal importation of oysters from Maine.

MATERIALS AND METHODS

Collection of Populations

Gill or mantle tissue was collected from adult *Ostrea edulis* oysters (>3 y old) using nonlethal sampling techniques (biopsy), and was preserved in 95% ethanol or by freezing at -20°C until DNA was extracted. Samples were taken from 10 sites in 2002 and 2003, which included hatchery stocks from Nova Scotia and British Columbia as well as naturalized populations in Maine (Welsh

* Corresponding author. E-mail: vercaemerb@mar.dfo-mpo.gc.ca

1964), New Brunswick and Nova Scotia (Fig. 1). Figure 1 also summarizes what is known about the various transfer and founding events associated with these populations within Nova Scotia and New Brunswick. As is frequently the case, many of the founding events and transfers are poorly documented. The Maine naturalized populations resulted from the importation of Netherlands oysters in the 1950s (Welsh 1964). In the 1960s, interest in *O. edulis* cultivation developed and several small hatcheries and oyster farms established themselves around the naturalized populations in Maine. The Boothbay and Cundy Harbor populations are older naturalized populations, whereas the Blue Hill Bay population is a more recent "naturalized" population that originated from importations from Boothbay Harbor and from California (Sam Chapman, pers. comm.).

After a small scale unsuccessful importation in the late 1960s to early 1970s from Maine to Nova Scotia, new naturalized oysters from Maine, and a few from North Wales, were imported in 1978 and 1979 to the Dalhousie University hatchery (Halifax, Nova Scotia) (Newkirk, 1986). In 1989 and 1994, respectively, the Dalhousie University and Nova Scotia provincial hatcheries closed and the broodstock was passed on to a total of four small commercial hatcheries, which, in conjunction with several grow-out operations have maintained most of the *O. edulis* cultured populations in Nova Scotia. In one grow-out site (Sambro), a small sustainable natural population managed to establish itself and has survived despite the closure of the grow-out operation. *O. edulis* were also found in Blind Bay, another former grow-out site. However, in this case, no juvenile oysters were recovered, and the few large oysters found appeared to be the last surviving oysters from the grow-out site after its closure. In 1996/1997, a naturalized population was established in Lake Lockhart, New Brunswick with oysters derived from the last two hatcheries left in Nova Scotia (Port Medway and Lunenburg). The Lake Lockhart population has grown rapidly and undergone two generations in the wild. It is the largest naturalized European oyster population in the Maritimes region of Canada. The Pacific Coast stock, sampled for comparison purposes, is a hatchery maintained stock of a mixed and poorly documented origin. Transfers have occurred in the last 20 years

with individuals originating from California, Scotland and Maine probably via Nova Scotia.

Amplification and Visualization of Microsatellites

To prepare the samples for DNA extraction, frozen tissue was thawed at room temperature. Both frozen and ethanol-preserved samples were rinsed in distilled water to remove residual salt from the tissue. DNA was extracted using DNeasy Tissue Kits, following the manufacturer's instructions (Qiagen cat #69506).

Polymerase Chain Reaction (PCR) was used to amplify 5 variable tandem repeat loci (microsatellites): 4 dinucleotides *OeduU2*, *OeduT5*, *OeduO9*, and *OeduJ12*, and 1 tetranucleotide, *OeduH15* developed at IFREMER (Launey 1998, Launey et al. 2002). Primers were labeled at the 5' end with a fluorescent dye. Eight microliters of reaction mix (10 μ M of each primer, 15 mM $MgCl_2$, 1 μ l 10 \times buffer, 1 μ l dNTP mix, and 0.5 u *Taq* polymerase) was added to 20–40 ng of DNA from the extraction. PCR amplification was performed using a MJ Research Dyad thermocycler (model PTC-220). A touchdown PCR was used to increase the specificity of the reaction (cycling conditions: an initial denaturation step at 94°C for 2 min, followed by 1 cycle at target annealing temperature (T_a) +5°C for 1 min, with subsequent decrease of 1°C/cycle for the next 4 cycles, with the remaining 25 cycles at T_a and a final 5-min extension at 72°C).

PCR products were electrophoresed on a 0.075 mm 5% denaturing polyacrylamide gel with an internal size standard (Megabase ET-400, Amersham-Pharmacia cat #25-0205-01) added to each lane. Electrophoresis and visualization of alleles were performed using a MJ Research BaseStation Fragment Analyzer. Alleles were assigned scores (size in base pairs) by comparing them to the internal size standard using Cartographer software (Cartographer v 1.2.6, MJ Research). To standardize scores obtained in this study with Launey et al (2002)'s study, 12 individuals genotyped at the IFREMER station in France on a Licor platform were selected for their wide range of allele sizes at each locus. These individuals, were also genotyped on the MJ Research BaseStation in Canada. The scores obtained from the two different platforms were compared and adjustments were made if required. Only two

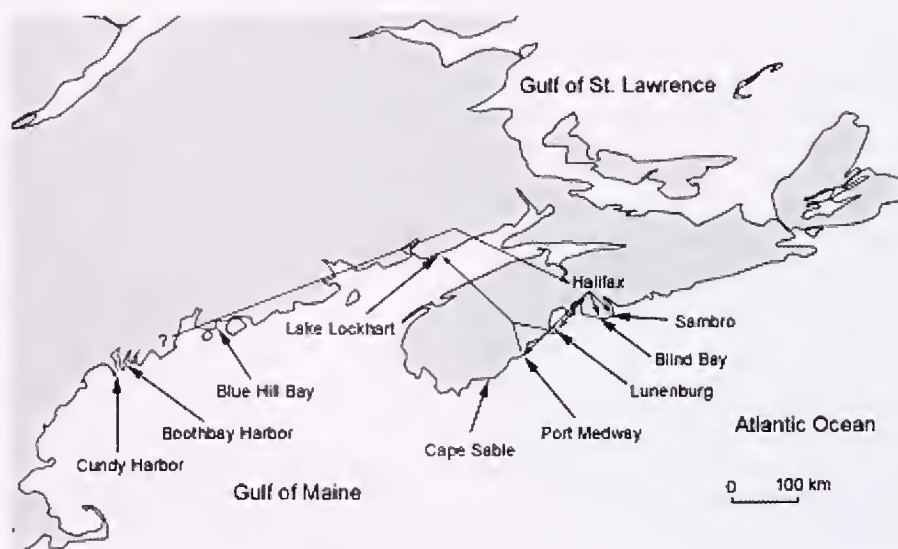

Figure 1. Map showing sampling locations and transfers of *Ostrea edulis* (long thin arrows indicate transfers to and within Nova Scotia and to New Brunswick)

microsatellite markers (*OeduJ12* and *OeduH15*) could be unambiguously standardized over the complete range of allele sizes.

Data Analysis

Observed and unbiased expected heterozygosities, F-statistics and genetic distances were calculated with the program GENETIX (Belkhir et al. 1996–2004) and the program CONTRIB (Petit et al. 1998) was used to calculate allelic richness corrected for differing sample size. The software MICRO-CHECKER (Van Oosterhout et al. 2004) was used to check for the potential presence of null allele and genotyping errors in the data set. PHYLIP (Felsenstein 1993) was used for drawing phylogenetic trees among the various populations. Phylogenetic analyses were based on all five loci when looking at genetic differentiation among the North American collections alone, but were based on two loci (*OeduH15* and *OeduJ12*) when using the European populations genotype data collected in an earlier work (Launey 1998, Launey et al. 2002).

In addition, 10 oysters from each of the three Maine collections were selected at random and removed from the database. These 30 oysters were then treated as an “unknown” sample to see to which populations they would be assigned on the basis of their genetic profiles using GENECLASS (Cornuet et al. 1999). The computation is based on a likelihood method using a Bayesian approach and gives for each individual a list of populations for which the “probability of belonging” is larger than a chosen threshold. We used the default probability of 0.01.

Lastly, DNA marker based pedigree reconstruction among the various collections of oysters was undertaken using Pedigree 2.2, a much expanded version of the pairwise score method (Smith et al. 2001, Butler et al. 2004), accessible online at <http://herbinger.biology.dal.ca:5080/Pedigree>. This approach to first generation pedigree reconstruction uses a highly efficient Markov Chain Monte Carlo algorithm to sample the space of possible partitions and to maximize an overall partition score based on the logarithm of pairwise likelihood ratios of being full-sib or unrelated. A partition is an allocation of all individuals into putative groups. Here, the individuals in the various oyster collections were allocated into putative kin groups, where a kin group contains individuals that appear related based on the DNA marker data but without imposing a particular type of relationship among the individuals. Individuals within kin groups are typically a mixture of full-sibs and half-sibs. This analysis was performed only on individuals with at least four loci genotyped and used the following MCMC parameters: 3000,000 iterations, annealing temperature of

10 and a weight of 1, because the various data sets did not appear to contain large family groups (see help manual available at <http://herbinger.biology.dal.ca:5080/Pedigree>).

Most pedigree reconstruction algorithms tend to assemble, by chance, unrelated individuals into small artefactual groupings (Smith et al. 2001, Butler et al. 2004). To test whether the kin group partitions generated for each oyster collections may contain at least a few truly related individuals, 100 genotype randomization trials were performed, followed by kin group reconstruction for each data set. This created 100 sets of unrelated individuals sampled from populations with the same genotypic frequencies as in our original datasets. The overall significance (*P* value) of a kin partition was evaluated by the proportion of the 100 randomized trials with a partition score as high or higher than the observed score.

RESULTS AND DISCUSSION

Allelic Variability, Allelic Richness Corrected for Sample Size and Allelic Frequencies

The five microsatellite loci used in this study were all found to be highly polymorphic. Allelic richness is highly dependent on effective population size (Nei et al. 1975) and should be a good indicator of past demographic changes (Petit et al. 1998). The number of alleles found at each locus ranged from 14 (*OeduH15*) to 29 (*OeduU2*), with a mean of 22.8.

Table 1 compares the observed number of alleles in the Canadian, Maine and Northern European populations overall. The observed number of alleles was lower in the Maine populations compared with the Northern European populations (data from Launey, 1998) at four of the five loci used in this study. The loss ranged from three alleles (*OeduH15*) to five alleles (*OeduU2*). The Canadian populations showed an even greater loss of allelic diversity, ranging from three alleles (*OeduH15*) to nine alleles (*OeduO9*), when compared with the Northern European populations. This was true despite the fact that the sample size for the Canadian populations was much larger than the Maine and European populations.

When the Canadian populations were compared with the Maine population, there was a loss of alleles at 3 loci: 2 alleles at *OeduU2*, 6 at *OeduT5*, and 5 at *OeduO9*. There was no loss of alleles at *OeduH15*, and a “gain” of an allele at *OeduJ12*. This “gain” is likely an artifact caused by the lower number of individuals from Maine.

Direct comparisons of allelic richness between populations was

TABLE 1.

Number of individuals genotyped and the number of observed alleles for the combined Canadian and Maine populations. Data for the Northern European populations of *Ostrea edulis* were obtained from Launey (1998).

Locus	Canadian Populations		Maine Populations		North European Populations (Launey, 1998)

Average		19.2		21.6		24.8

difficult because of the large range in sample sizes (30–148), because larger samples will have a greater chance of including rare alleles. The program CONTRIB was used to correct for differences in sample size. Table 2 illustrates the amount of genetic diversity present in each of the sampled populations by showing the actual and corrected numbers of alleles at each locus. The NS hatchery stocks had a mean corrected number of alleles ranging from 9.91 (Port Medway) to 10.32 (Lunenburg). The British Columbia hatchery stock was slightly more diverse (11.20), and Maritimes naturalized populations varied from 8.88 (small "naturalized" Blind Bay group, which shows the lowest mean number of corrected number of alleles) to 12.81 (Lake Lockhart) alleles. The Maine populations ranged from 12.43 (Blue Hill Bay) to 15.29 (Boothbay Harbor).

At each locus, evidence of some genetic erosion can be seen with smaller number of alleles observed in the Canadian collections. Compared with the 2 larger Maritimes naturalized populations (Sambro, NS and Lake Lockhart, NB) and to the Maine naturalized populations (Cundy's Harbor, Boothbay Harbor and Blue Hill Bay), the combined Nova Scotian hatchery stocks (Lunenburg, Port Medway and Cape Sable) showed the lowest number of alleles at all loci, with a mean of 13.6 alleles for all loci. The Maritimes naturalized populations showed a mean of 17.6 alleles and the Maine populations a mean of 21.6 alleles. Nevertheless, the actual number of alleles at each locus was still relatively high in the Nova Scotia hatchery stocks.

Some degree of on-going genetic erosion is therefore taking place in the artificially propagated populations of *Ostrea edulis*, but it would appear that as of 2002–03 there is still a substantial level of genetic diversity in the Canadian collections, despite the fact that these populations have been isolated from both their ancestral European and Maine populations and have been propagated in hatcheries for several generations. As a comparison, in *O. edulis*

French populations selected for *Bonamia* resistance, the mean number of alleles was reduced from 19.8 (natural population) to a range of 5.4–12.8 (selected populations) in two generations (Launey et al. 2001). The Canadian populations seem to have experienced considerably less erosion of allelic richness in 6–7 generations since their importation from Maine. In other words, genetic erosion could have been more drastic than was revealed in this study.

Genetic erosion is a common concern for hatchery stocks. An estimation of the breeding number of oysters in hatchery *Crassostrea virginica* MSX resistant lines varied from 4–16 (Hedgecock et al. 1992). Hatchery-propagated Pacific oysters have also lost alleles in three generations and one hatchery stock showed a per-generation effective population size of 9 oysters (Hedgecock & Sly 1990). Boudry et al. (2002) showed that effective population size was strongly reduced compared with census size in *Crassostrea gigas* because of unbalanced parental contribution. For *O. edulis*, Launey et al. (2001) estimated that the effective size of oyster populations selected for *Bonamia* resistance was very low, between 3 and 20 at the most. In the present study, effective population size N_e could not be determined but was probably higher than in the populations studied by Launey et al. (2001). Alvarez et al. (1989) and Saavedra and Geera (1996) previously reported the number of effective *O. edulis* broodstock to be 6–10 and 3–4 from mass spawning tanks containing 60 and 120 animals respectively. This evidence shows that *O. edulis* is a species susceptible to founder and bottleneck effects in the hatchery environment and that genetic erosion has to be carefully monitored.

In this study, the allelic richness corrected for unequal sample size clearly indicated that the Lake Lockhart population was the most diverse in the Canadian collections. This is probably because of the fact that it is a relatively large, truly naturalized population. Although sampled from the wild, the Blind Bay population did not

* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$

appear as variable as the two other naturalized Nova Scotian populations. This is a probable indication that it is not a truly naturalized population. Divers at this site did not find any juvenile oyster or any sign of recruitment. The few large oysters found there were probably the last survivors of the previous cultivated oysters. The five remaining Canadian populations appeared similar, with possibly a slightly higher diversity in the Pacific Coast stock. Repeated transfers have occurred in the last 20 years with individuals originating from different populations in California, Scotland and Maine, possibly explaining the higher diversity in this hatchery stock.

The allelic profiles for each locus showed multimodal distributions both in the Maine population and the Canadian population as they did in Europe (Launey 1998). Only the distribution for *OeduO9* was close to a normal distribution in a European sample of 507 individuals (Launey 1998). There was no major discontinuity in the distributions and increments corresponded to the repeat length for a given locus (dinucleotide for all loci except *OeduH15*, which is a tetranucleotide locus). However the various collections showed differences in the abundance of rare alleles (frequency $<10\%$). A high level of rare alleles (87% average over 5 loci) characterized the Maine population, whereas the Maritimes naturalized populations and hatchery stocks showed lower levels of 73% and 69% respectively. The hatchery populations lost 5, 2, 7, 8 and 2 rare alleles at loci *OeduU2*, *OeduH15*, *OeduT5*, *OeduO9* and *OeduJ12* respectively compared with the naturalized popula-

tions. These results are usually observed when a population experiences a bottleneck event but may also reveal subsequent genetic erosion.

Heterozygosity

The observed heterozygosity (H_o) was lower than the expected heterozygosity (H_e) for all populations (Table 3), a typical observation in bivalves (Hedgecock et al. 1992, Hedgecock & Okazaki 1984). The difference between H_e and H_o was smallest in the British Columbia and Port Medway samples. This may be a result of a breeding program for certain traits that has led to the incidental selection of heterozygotes, or may possibly be an artifact of the sampling procedure, because the sample sizes for these populations were both relatively small.

When looking at the hatchery stocks (Table 3), levels of heterozygosity were not as dramatically reduced as allelic richness was. The average observed heterozygosity (H_o) for each population ranged from 0.670 (Lunenburg) to 0.827 (British Columbia) and no apparent association between the observed heterozygosity and the origin of the samples (hatchery vs. naturalized) was observed. Similar results have been reported for many cultivated populations (Herbinger et al. 2003); in particular an earlier study on *Crassostrea gigas* showed that the number of alleles was significantly reduced but heterozygosity was retained in hatchery stocks compared with naturalized populations (Hedgecock & Sly 1990, Herbinger et al. 2003).

^{NS}: $P > 0.001$

The F_{is} values for the five loci, all populations combined, ranged from -0.094 (*OeduT5*) to $+0.585$ (*OeduH15*) (Table 3), which represents a large range of values. The estimated F_{is} values varied much less among samples (from $+0.040$ to $+0.179$) than among loci. This result indicates that inbreeding is not the sole explanation for the heterozygote deficiencies. All populations showed mostly positive F_{is} values revealing deficits in heterozygosity, but this was really mostly prevalent for loci *OeduH15* and *OeduJ12* (Table 3). Such observations are common in bivalves (Zouros & Foltz 1984) and the same pattern was observed in the European populations (Launey 1998). This is likely due mostly to the presence of null alleles (alleles that are not amplifying, possibly caused by a mutation in the primer site). Indeed, MICRO-CHECKER revealed the probable presence of null alleles for *OeduH15* and *OeduJ12* in nearly all populations. Launey (1998) also hypothesized that null alleles were present for the locus *OeduH15*. *O. edulis* natural populations have high fecundity and potentially large dispersal of gametes and larvae, and so should follow the HWE assumptions for panmixia. In the context of the hatchery-propagated populations, heterozygotes deficit could possibly also reflect blind selection effects, along with small reproductive population size and inbreeding (Hedgcock 1994). However, given the relative similarities of the F_{is} values observed in naturalized and hatchery population, it would seem that the presence of null alleles at loci *OeduH15* and *OeduJ12* are the main reasons for the observed heterozygote deficiencies here.

Genetic Differentiation Between European Oyster Populations

The genetic differentiation between populations revealed by the pairwise F_{ST} values are displayed in Table 4. Most of the F_{ST} values under 0.027 were not significant and indicated negligible genetic differentiation. This can be illustrated graphically with an unrooted tree constructed using the coancestry distances (Reynolds et al. 1983) (Fig. 2a). The Maine populations clustered together with the Pacific Coast population, probably reflecting the founding events that led to the establishment of the Pacific Coast population through the transfer of oysters from California, Scotland and Maine. Despite their recent origin, the Maritimes populations (Port Medway, Lunenburg, Lake Lockhart and Cape Sable) clustered together and were quite divergent from the Maine populations. The intermediate position of the Sambro oysters possibly reflects the fact that they are an older renaturalized population consisting of Maine oysters that were maintained at Dalhousie University in Halifax for several years before being released. The close clustering of the Nova Scotian populations is explained by their recent common ancestry and the exchanges of individuals that have taken place between these populations. For example, the fact that the Lake Lockhart and Lunenburg populations cluster closely together reflects the fact that the Lake Lockhart population was established using mainly oysters from Lunenburg stocks.

The Northern American flat oyster populations were compared with 5 European populations of flat oysters representing 4 subregions of the sampling realized in Launey et al. (2002), (ANa from Oslofjorden, Norway (North Atlantic); ANb from Grevelingen, Netherlands (North Atlantic); ASb from La Rochelle, France (South Atlantic); MWb from Thau Lagon, France (West Mediterranean Sea); MEb from Dubrovnik, Croatia (East Mediterranean Sea)). The analyses were based on the 2 microsatellite markers (*OeduJ12* and *OeduH15*) that could be unambiguously standardized between the genotyping systems from the Canadian and

Figure 2. Canadian and Maine populations (5 loci) b. Canadian and North Atlantic European populations (2 loci)

French molecular laboratories. The resulting neighbor-joining tree is visualized in Figure 2b. The sample from the Netherlands (ANb) showed F_{ST} values not significantly different from 0 with 2 Maine populations (Cundy Harbour and Boothbay Harbour) confirming the Netherlands as the probable origin of the introduction of the European flat oyster on this Northern American region of Maine (Loosanoff, 1955). Although significant, the F_{ST} values between the North Atlantic sample from Norway (ANa) and each of the Northern American populations were also small. The neighbor-joining tree clearly shows that the sample from Norway (ANa) is clustering (all the bootstrap values were superior to 50%) with the

samples from Nova Scotia, indicating a possible second distinct introduction from Europe. It should be noted however that this analysis is based on only two loci with probable null alleles. Hence, this should be seen as a preliminary indication only and such analysis should be extended with more loci.

Assignment of Maine Individuals

Assignment of the 30 Maine individuals on the basis of their genotype was overall satisfactory (Table 5) even though this was based on 5 loci, and the genetic isolation between Maine and Nova Scotia populations is fairly recent. Nine individuals could not be definitively assigned to a population but 19 were correctly identified as originating from a Maine population only and 2 were assigned to another Maine population or to a Nova Scotia naturalized population. Among those 21 individuals, 15 were assigned to the specific Maine population they originated with either the highest likelihood (8 cases) or the second highest (7 cases). It should be noted that most of the individuals from Blue Hill Bay were assigned to another population of Maine or to a renaturalized population in Nova Scotia. That particular population could have been founded with individuals originated from other parts of Maine and from California (Sam Chapman, pers. comm). In addition, Blue Hill Bay is the Maine population the least different from the Canadian stocks (Fig. 2a). The assignment results presented here show both promise as a forensics tool and some limitations. With a larger database and more microsatellite loci, more definite results could probably be achieved. Nonetheless, the present tool would seem to be able to detect illegal importation of Maine oysters that could bring the *Bonamia* disease into Nova Scotia.

First Generation Pedigree Reconstruction

Most of the kin groups detected in the 10 oyster collections were very small, ranging in size from 1–11 with an average of 2.5 individuals, indicating that overall, most individuals were unrelated to one another in every collection. However, at least some of these small proposed kin groups appeared to be real, because in 6 out of the 10 populations the kin group partition score, based on the real genotype data, was higher than seen in any of the 100

genotype randomization trials (Table 6). Not surprisingly, every hatchery population seemed to comprise at least a few truly related individuals (i.e., full or half-sibs). This was particularly the case for the Port Medway and Cape Sable collections. This is in agreement with the observations of Li & Hedgecock (1998) and Boudry et al. (2002) who have noted that hatchery mass spawning typically contains large, over-represented family groups. In contrast, the naturalized populations of Cundy Harbor (Maine), Booth Bay (Maine) and Sambro (Nova Scotia) did not appear to contain related individuals. The last naturalized Maine collection, Blue Hill Bay, may have contained some related individuals, but the signal from this analysis was fairly weak and the probability value was close to the 5% threshold. Some of the "naturalized" individuals in the Blind Bay (Nova Scotia) collection also appeared to be related

TABLE 6.

(1) Sample size

(2) Probability estimated on 1,000 randomization trials, as opposed to 100 in the other collections

to one another. This would be in agreement with the proposed explanation that this population is not truly self sustaining, and that the sampled individuals probably represented the last survivors of "escaped" cultured oysters from a grow-out site that operated there until a few years ago. The observation of truly related individuals in the Lake Lockhart (New Brunswick) collection is more surprising because this is a fairly large, self-sustaining population. To confirm this result, the genotype randomization trials were extended to 1,000 but with similar results. Partition scores as high or higher than the one observed on the real data, were only seen in 2 out of the 1,000 trials. It is unlikely that oyster sampling in this location was somehow biased with respect to family composition as it took place with bottom dredging. This observation may be an indication that a few individuals may sometimes contribute a substantial (i.e., detectable) portion of the recruitment in the large but closed Lake Lockhart population.

CONCLUSION

The results of this study show that there is still a relatively high level of genetic diversity in the Canadian populations, but evidence of genetic erosion can be seen in the hatchery-propagated stocks. Some level of inbreeding increase occurs in hatchery populations of *Ostrea edulis* around the world, and there is evidence to suggest that excessive inbreeding can result in loss of fitness. For instance, Mallet & Haley (1983) and Naciri-Graven et al. (2000) have observed that growth performance of offspring is negatively correlated with the relatedness of their parents. Using microsatellite loci to monitor inbreeding levels would appear to be warranted.

Increasing the number of loci available for use in *O. edulis* would be useful for continuing and future studies of genetic diversity and population structure in this species and for forensics studies given the presence of *Bonamia* in Maine and its absence so far in Nova Scotia and New Brunswick. Increasing sample size will also improve our ability to detect population and family structure more effectively.

Hatchery production for aquaculture allows the development of genetically improved strains but, simultaneously, loss of genetic diversity and potential inbreeding increase and inbreeding depression can have adverse effects. To manage inbreeding, it is impor-

tant to use pedigree information when producing the next generation. Because of the reduced number of effective broodstock in mass spawning, where only a limited number of individuals contribute most of the offspring to the next generation, it may be wise to increase genetic variability in hatchery populations by maximizing the number of *O. edulis* broodstock used to produce larvae (at least 50 per lot, preferably 100) and pooling offspring from multiple spawning groups (i.e., multiple lots). The genetic impact of grading larvae and discarding the small ones, a common hatchery practice, should be evaluated. This practice may compound genetic erosion without really achieving any growth gain. The possibility of introducing individuals from naturalized populations at regular intervals to maintain genetic diversity and prevent further erosion of genetic diversity in Nova Scotia hatchery stocks should be evaluated as well. Outbreeding of *O. edulis* should be carried out within Maritimes populations as opposed to more distant populations to reduce the possibility of disease transfer and also to avoid the introgression of nonadapted genes into the actual stocks. In particular, history shows that only after a 30-year adaptation to Maine's cold environment did introduced European oysters survive in Nova Scotia's marginal winter conditions.

ACKNOWLEDGMENTS

The authors especially thank Barry MacDonald (DFO – Bedford Institute of Oceanography) for his support and Andrew Bagnall (NS Department of Agriculture and Fisheries – Aquaculture Division); Thomas Landry (Gulf Fisheries Centre) and Dale Wilbur, Gary Meyer and Susan Bower (DFO-Pacific Biological Station); Cathy Enright (Nova Scotia Agricultural College) and Chris Davis (Maine Aquaculture Training Institute) for collection of oysters. This manuscript was greatly enhanced from comments by two anonymous reviewers. This study has been funded under the Aquaculture Collaborative Research and Development Program (ACRDP) and involved two hatcheries Lunenburg Shellfish Inc. and Har-Wen Farms in Port Medway. A technical report with raw data has been produced under that program (Vercaemer et al. 2003), it reflected an active collaboration between DFO and IFREMER (Institut français de recherche pour l'exploitation de la mer).

TISSUE DISTRIBUTION AND HEMOLYMPH ACTIVITY OF SIX ENZYMES IN THE AMERICAN LOBSTER (*HOMARUS AMERICANUS*): POTENTIAL MARKERS OF TISSUE INJURY

ANDREA BATTISON

Atlantic Veterinary College Lobster Science Centre (AVCLSC), University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

ABSTRACT Biochemistry panels are used to help identify tissue injury (e.g., because of inflammation, trauma or hypoxia) in human and veterinary medicine in part, by detecting increased enzyme activity in serum or plasma after release from damaged tissues. To determine if a similar approach can be used in *Homarus americanus*, activities of aspartate aminotransferase (AST), alanine aminotransferase (ALT), glutamate dehydrogenase (GDH), sorbitol dehydrogenase (SDH), amylase (AMY) and lipase (LIP) were measured in tissue homogenates of heart, hepatopancreas, abdominal muscle, proximal intestine, antennal gland, hemocyte lysate supernatant and hemolymph plasma and serum. Activities of ALT and AST were significantly higher in serum than plasma, which was attributed to release of enzymes from hemocytes during coagulation. Reference intervals calculated for plasma enzyme activity at ambient holding temperatures of 2°C to 4°C and 15°C were quite similar. Plasma enzyme activity was not a sensitive test for detecting infection with *Aerococcus viridans* (gaffkemia) during an experimental trial.

KEY WORDS: lobster, *Homarus americanus*, enzyme, hemolymph

INTRODUCTION

The lobster fishery is a multimillion-dollar industry in Atlantic Canada and the northeastern USA. The landed value of the ~42 K mt harvest in Atlantic Canada in 2004 is estimated at ~\$525,077 K (Cdn)¹. The overall economic impact to the region of this vital industry is far greater. Although much of the harvest is sold or processed immediately, a portion is held live, for several weeks to months, in lobster pounds for sale as live product at a later date. Significant losses to disease can occur during these periods. Consequently, being able to assess the health status of these animals, as a means of selecting those best suited for storage, is very beneficial.

Current methods of health assessment in *Homarus americanus* (H. Milne Edwards 1837) and many other crustaceans include: physical examination to determine vigor; total hemocyte counts (THCs); estimating total hemolymph protein concentration using refractometry (TP_{tr}) and hemolymph culture to detect infective agents (bacteria, protozoa). Evaluation of the cell-free fractions of hemolymph, i.e., plasma and serum, in *H. americanus* has included electrolyte and metabolite levels (Mercaldo-Allen 1991, Mercaldo-Allen et al. 1994) and enzyme activity (Speare et al. 1996). Evaluation of hemolymph enzyme activity in mussels and oysters has been suggested as a nonlethal way of assessing overall health, and possibly immune function, as in human and veterinary medicine (Culloty et al. 2002, Gustafson et al. 2005).

Clinical enzymology can be thought of as the “application of the science of enzymes to the diagnosis of disease” (Moss & Henderson 1999). The level of enzyme activity detected in the blood is related to the rate of release or production of enzyme(s) from tissues and their clearance from the circulation (Moss & Henderson 1999). Some enzymes are relatively tissue specific, being found in only one or a few tissues, whereas others can be more widely distributed among several tissues (Duncan et al. 1994a, Kramer & Hoffmann 1997, Moss & Henderson 1999). There will usually be low levels of enzymes in the blood caused by steady-state release from tissues. These values are used to calculate

reference intervals, or “normal ranges,” for a defined (age, sex, race, geographic distribution, disease status, etc.) population. These reference intervals are then used as a basis for comparison with individuals or groups under study. When the tissue is injured (trauma, toxins, inflammation, hypoxia) the cellular integrity will be compromised and more enzyme will be released into the circulation, exceeding the upper limit of the previously established reference interval (Kramer & Hoffmann 1997, Moss & Henderson 1999). The degree of increase will be determined by the amount of tissue injured, the severity of the injury, and the clearance rate of the enzyme from the circulation.

The purpose of this investigation was to determine if the principles of clinical enzymology could be applied to *H. americanus*. This required: (1) determining the tissue distribution of a selected group of enzymes; (2) determining the preferred sample type, plasma or serum; (3) establishing hemolymph reference intervals for enzyme activities in a defined population and (4) examining if hemolymph enzyme activity was affected by a systemic bacterial infection, gaffkemia.

The activity of aspartate aminotransferase (AST), alanine aminotransferase (ALT), sorbitol dehydrogenase (SDH), glutamate dehydrogenase (GDH), amylase (AMY) and lipase (LIP) was determined in homogenates of hepatopancreas, heart, abdominal muscle, proximal intestine, antennal gland, hemocyte lysate supernatant (HLS) and hemolymph plasma and serum. Enzymes were selected for the biochemistry panel based on the availability of commercial diagnostic test kits compatible with an automated biochemistry analyzer and their known or presumed presence in hepatopancreas and muscle (Claybrook 1983, Biesiot & Capuzzo 1990)—tissues similar to those contributing significantly to serum and plasma enzyme activity in vertebrates (Kramer & Hoffmann 1997, Moss & Henderson 1999). Clotting in *H. americanus* and other crustaceans involves hemocyte lysis (Martin & Hose 1995). Consequently, HLS was evaluated for its possible contribution to serum enzyme activity. The proximal intestine, antennal gland, and heart were included for completeness. Gaffkemia, a generally fatal infectious disease caused by the Gram positive bacterium *Aerococcus viridans*, can cause significant economic losses in the industry (Hastein & Roald 1977, Stewart 1980, Menard & Myrand 1987). Early detection could provide critical informa-

tion for management decisions and help minimize postharvest losses.

MATERIALS AND METHODS

Animals and Holding

Tissue Enzyme Distribution Study

Four (3 female, 1 male) hard shell, southwest Nova Scotia inshore lobsters weighing 404–499 g were obtained from a commercial pound (Clearwater Fine Foods Inc., Halifax, NS, Canada). The animals were held in a recirculating artificial sea water (ASW) (Instant Ocean, Aquarium Systems Inc., Mentor, OH, USA) system maintained between 2°C to 4°C for up to 12 d. Lighting was set at a 14 h/10 h low light (<3 lux)/dark cycle. Animals were not fed during this period.

Establishment of Reference Intervals and Gaffkemia Trial

Thirty male southwest Nova Scotia offshore lobsters weighing 597–791 g were obtained from a commercial source (Clearwater Fine Foods Inc., Halifax, NS, Canada). The animals were held in a recirculating ASW (Instant Ocean, Aquarium Systems Inc., Mentor, OH, USA) system maintained between 2°C to 4°C for 9 d then moved to a second recirculating ASW system at 15°C. Lighting was set at a 14 h/10 h low light (<3 lux)/dark cycle. Animals were offered a pelleted lobster diet (Castell Aquaculture Nutrition Consulting, St Andrews, NB, Canada) every other day when at 15°C.

Biochemical Analyses

All samples for biochemistry panels were analyzed on the Hitachi 917 automated biochemistry analyzer (Roche Diagnostics Corporation, Indianapolis, IN, USA) within three hours of collection. Assay kits for GD, AST, ALT and total protein (TP) were obtained from Roche Diagnostics Corporation, Indianapolis, IN, USA. Assay kits for LIP and AMY were obtained from Diagnostic Chemicals Limited, Charlottetown, PE, Canada.

Assay precision was determined by measuring enzyme activity in 20 aliquots of two samples, one with high enzyme activity and one with low activity. The coefficient of variation (CV) was calculated for each sample.

Tissue Enzyme Distribution Study

Hemolymph samples were collected (22 G needle) from the ventral sinus 2 d after arrival as part of a health screen. A 0.5-mL sample was collected into 4.5 mL of formalin-containing anticoagulant (28.4 g/L NaCl, 8.7 g/L $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 5.5 g/L $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 1.5 g/L $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.7 g/L KCl, 0.5 mL Tween 80, 1.25 mL/L stock [37% to 40%] formaldehyde solution, pH 7.6, Stewart et al. 1967) for determination of THC's using a Neubauer hemocytometer. Whole hemolymph (no anticoagulant) was collected for TP_{tr} estimation using a temperature compensated refractometer (Shilac ATC PUR1410, Japan) and inoculation of culture media to detect *A. viridans* (0.5 mL in 4.5 mL phenyl ethyl alcohol [PEA] broth at 28°C for 48 h, in duplicate, Stewart 1972) and *Anophryoides haemophila* (0.5 mL into 4.0 mL of modified ciliate culture medium at 4°C for 7 d, Messick & Small 1996). Pleopods were collected for molt staging (Aiken 1973). Animals were processed after confirmation of negative culture results and $\text{THC} > 10 \times 10^9$ cells/L and $\text{TP}_{\text{tr}} > 50$ g/L.

Immediately prior to processing, a terminal hemolymph col-

lection (approximately 30 mL/lobster) was performed to obtain hemocyte pellets for HLS preparation. The supernatant (plasma) was removed after centrifugation ($\times 3300$ g, 15 min at 4°C) and the pellet rinsed with sterile distilled water. Lobsters were euthanized by severing the ventral nerve cord in front of the walking legs. Samples of hepatopancreas, heart, antennal gland, proximal intestine and abdominal muscle were collected and immediately placed on ice. The contents of the intestinal lumen were removed by gentle rinsing with distilled water. Tissues (≤ 0.5 g) were then minced with a scalpel blade after addition of 5 mL of sterile distilled water, transferred to a glass piston homogenizer and ground until no large particles remained. Samples were left to lyse, refrigerated, for 1 h. Tissue homogenate supernatants were prepared by centrifugation ($\times 15,000$ g, 20 min, at 4°C) and assayed for enzyme activity and TP (biuret method) concentration. Enzyme activity per gram of total protein was calculated to standardize the results among tissues.

Comparison of Plasma and Serum Samples

Hemolymph was collected (22 G needle, no anticoagulant) from the ventral sinus of the four lobsters used for the tissue enzyme distribution study. Plasma was prepared from one 1.8 mL aliquot. Serum was prepared by allowing refrigerated 1.8 mL aliquots to clot. After 5 h and 22 h, the samples were broken up and centrifuged ($\times 5000$ g, 5 min, at 4°C) and the supernatants collected and submitted for biochemistry panels.

Establishment of Reference Intervals

Hemolymph samples for THC's, TP_{tr} , biochemistry panels and inoculation of PEA were collected from the ventral sinus of 30 male, hardshell lobsters 2 d and 6 d after their arrival (2°C to 4°C) and again after being held at 15°C for 4 d. Pleopods for molt staging (Aiken 1973) and hemolymph for ciliate medium (Messick & Small 1996) inoculation were only collected at the first sampling. Reference intervals were calculated for the latter two sample collections using results from intermolt animals with $\text{THC} > 5 \times 10^9$ cells/L and negative hemolymph cultures.

Gaffkemia Infection Trial

Aerococcus viridans Inoculate Preparation

A thawed aliquot of a first passage subculture of a field isolate of *A. viridans* Type 3 (api 20 Strep, bioMérieux Canada Inc., St. Laurent, PQ, Canada), stored at -80°C in 2% skim milk culture broth (Bacto skim milk, DIFCO Laboratories, Detroit, MI), was grown on sheep blood (5%) agar (BA) (Oxoid, Inc. (Canada), Nepean, ON) at 28°C for 24 h and used to inoculate 25 mL of sterile trypticase soy broth (TSB). Broth cultures were incubated overnight at 28°C and the optical density was read at 420 nm. The suspension was washed ($\times 3600$ g, 10 min, at 4°C) twice with sterile 3% NaCl and an aliquot diluted to an expected concentration of 2×10^6 colony forming units (CFU)/mL. Colony counts were performed on $\times 25$ μm aliquots of serial dilutions cultured on BA at 28°C after 48 h of incubation to confirm inoculate dose.

The supernatant from a 24 h TSB culture of *A. viridans* was submitted for a biochemistry panel.

Experimental Protocol

Thirty male lobsters were acclimatized at 2°C for 10 d and then transferred into a new system at 15°C for 7 d. Hemolymph samples

were collected from the ventral sinus for determination of THC_s, TP_{tr} and biochemistry panels and a few drops of whole hemolymph were used to inoculate BA, incubated at 28°C, for detection of *A. viridans* bacteremia. Twenty lobsters with THC > 10×10^9 cells/L, and negative culture results were selected and randomly assigned into treatment and control groups. Control group lobsters were moved into a replicate system in the same room. Lobsters in the treatment group were inoculated (intra-abdominal sinus injection, 25 G needle) with *A. viridans* at $\sim 1 \times 10^6$ CFU/kg. Control group lobsters received a similar volume of sterile 3% NaCl. One sentinel lobster (no injection) was kept in each tank.

Hemolymph was collected daily for determination of THC_s, TP_{tr}, biochemistry panels and BA inoculation. A direct smear (DS) of hemolymph was also made and examined by direct light microscopy to detect bacteremia. The study was terminated after 5 d because all treatment group lobsters were bacteremic on DS exam.

Lobsters were euthanized by KCl injection (Battison et al. 2000). Post mortem examinations were performed. The hepatopancreas and antennal gland were sampled with sterile swabs (BBM CultureSwab Plus, Becton Dickinson, Basel, Switzerland) for culture on BA at 28°C for 48 h. Representative samples of hepatopancreas, proximal intestine, antennal gland, muscle, gonad and ventral nerve cord were collected and fixed in 1G:4F fixative (Howard & Smith 1983) and processed routinely for hematoxylin and eosin staining of paraffin sections.

Statistical Analyses

Statistical analyses were performed using the Minitab release 13 software package (Minitab Inc., State College, PA, USA) and Microsoft Excel 2002 (Microsoft Corporation, USA).

RESULTS

Precision Study

Precision results at the lower activity levels found in plasma were generally moderate to poor, ranging from 5% to 24% (Table 1). The value for SDH was very high (245%) as all but one of the 20 replicates returned a value of 0 U/L. Precision at the higher activity levels found in serum was acceptable, being below or near 5% in all cases.

** CV, coefficient of variation = standard deviation/mean * 100.

Tissue Enzyme Distribution

The hepatopancreas was the exclusive source of AMY in all but one lobster where it was also detected in the proximal intestine (Table 2). Moderate to high levels of AST and ALT were found in all tissues with the heart containing the most activity (Table 2). The highest GD activity was found in the heart with only low to moderate levels recovered from other tissues (Table 2). LIP activity was low, but primarily isolated from proximal intestine preparations (Table 2). SDH activity was low and widely distributed.

Comparison of Plasma and Serum

There was minimal or no AMY, LIP, or SDH in the plasma or serum samples. There were notable differences between the plasma and serum samples for AST, ALT and GD in all lobsters. In all instances, serum values were higher than plasma at both time periods (Table 3). The amount of increase varied with the individual lobster and the enzyme. Changes in ALT were usually the most marked, whereas GD was relatively stable. Serum enzyme activity at 22 h tended to be less than at 5 h.

Screening Samples and Establishment of Reference Intervals

Enzyme activity collected 2 d after arrival was quite variable with some lobsters having AST and/or ALT activities up to 10 fold greater than the values obtained from the same animals only 4 d later (Table 4). A similar, but much less dramatic, finding occurred with LIP (Table 4).

Enzyme activity in the two data sets used for reference interval calculation had a nonGaussian distribution except for GD at 15°C. After removal of outliers, results from 25 of the 30 lobsters sampled after 6 d at 2°C, and 26 of the lobsters sampled after 4 d at 15°C were used to calculate the plasma reference intervals using percentiles (Table 4).

Gaffkemia Infection Trial

Animals received inocula of $\sim 1.5 \times 10^6$ CFU/kg based on 48 h colony counts. A contaminant (*Acinetobacter* sp.) was detected in the inoculate suspension but not recovered from any lobsters. Bacteremia was detected on hemolymph culture in nine treatment group lobsters on postinoculation Day 2 and in all lobsters by Day 3. Four *A. viridans* colonies were detected in one control group lobster on Day 5 only. Bacteria were visible on DS in eight treatment group lobsters by Day 4 and in all by Day 5. A heavy growth of *A. viridans* was recovered from the hepatopancreas and antennal gland of all treatment group animals but no control group lobsters. Very low numbers of mixed bacteria were recovered from the antennal gland of nine, and from the hepatopancreas of three, control group lobsters.

THCs showed an initial increase Days 1–3 in treatment group lobsters followed by a decrease to $\sim 2 \times 10^9$ cells/L by Day 5 in most (8/10) lobsters as seen in previous studies (Stewart et al. 1969, Stewart et al. 1983, Battison et al. 2004). A progressive decrease in THC ($< 5 \times 10^9$ cells/L) was also noted in 5 of 10 control group lobsters. TP_{tr} decreased by 10% to 15% of initial values by the end of the study in all, but one control (49%), lobsters.

For most lobsters, enzyme activities stayed within the previously established reference intervals (Fig. 1). There was a tendency for LIP to decrease over the course of the trial for both groups. A few animals (treatment and control groups) had minimal increases in ALT. Mild to moderate increases in GD were ob-

served in 3 lobsters (2 treatment and 1 control). Elevations in SDH were limited to one treatment group lobster, which also had moderate increases in AST, ALT and GD and two control group lobsters—one of which had moderately elevated GD. Essentially no enzyme activity was detected in the TSB culture supernatant.

The main gross finding in the treatment group lobsters was the presence of multifocal to diffuse, white, milky, spots on the antennal gland. All of the control group lobsters showed variable degrees of pigmentation at the base of the gill filaments. Two treatment group lobsters had mild, focal, white discoloration of abdominal muscle segments (necrosis) near hemolymph collection sites.

Histological findings in the treatment group were consistent with gaffkemia (Johnson et al. 1981, Battison et al. 2004). Coccid bacteria in tetrads were present in the hemolymph spaces of all tissues. Small hemocyte nodules, some with phagocytosed cocci, were noted in low to moderate numbers in most tissues examined.

There was moderate to marked, multifocal to diffuse, involvement of the fixed phagocytes in the connective tissue of the hepatopancreas. The cells were enlarged and vacuolated, containing large numbers of bacteria and often surrounded by hemocytic

nodules (Fig. 2). Deposition of a red-orange, hyaline material was noted in some nodules (Fig. 2). The antennal glands were similarly affected with multifocal to coalescing septic, variably sized, hemocytic nodules. Moderate, focal, myonecrosis was confirmed in one lobster.

All control group lobsters had a moderate to severe necrotizing, nonseptic, melanizing, branchitis. Large hemocyte aggregates were present in many gill filaments sometimes filling the vascular channels, similar to a thrombus. Adjacent tissue was uniformly lightly eosinophilic (necrotic) in some sections. Infectious agents were not identified. Neither *A. viridans* nor lesions typical of gaffkemia were found in the one control group lobster which had a single positive hemolymph culture.

DISCUSSION

Clinical chemistry is an important diagnostic tool in human and veterinary medicine. The purpose of this investigation was to determine if this tool could also be applied to lobsters, and potentially other crustaceans. To interpret hemolymph enzyme activity, it was necessary to determine the tissue distribution of the enzymes in lobsters. This was important because enzymes that are tissue spe-

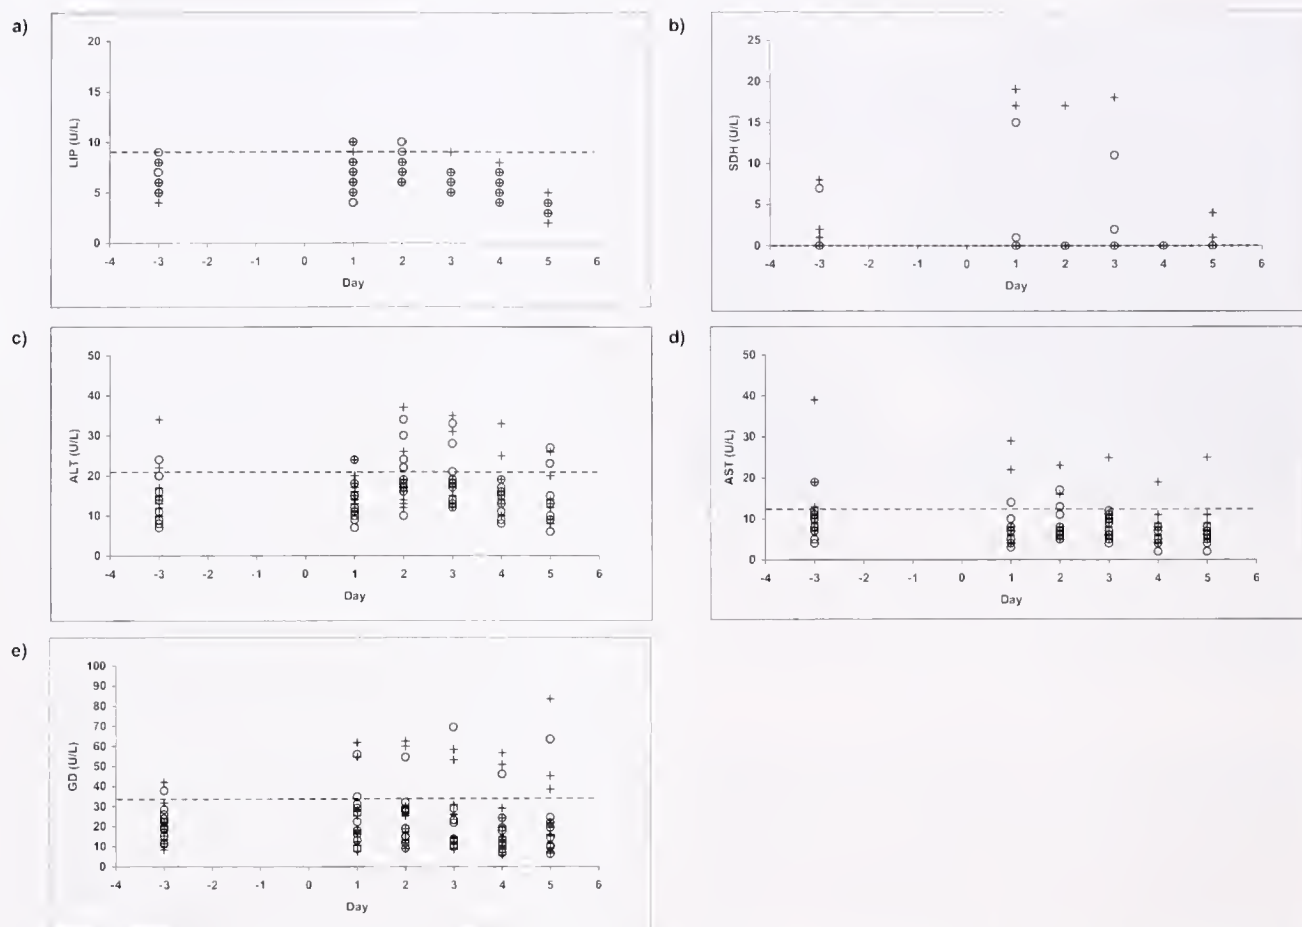

Figure 1. Plasma activity of: (a) lipase (LIP), (b) sorbitol dehydrogenase (SDH), (c) alanine aminotransferase (ALT), (d) aspartate aminotransferase (AST) and (e) glutamate dehydrogenase (GD) for lobsters (*Homarus americanus*) inoculated with *Aerococcus viridans* bacteria (+; $n = 10$) or 3% sterile NaCl (O; $n = 10$). Samples were collected prior (Day -3) to inoculation on Day 0 and daily during the trial (Days 1–5). The dashed line represents the upper limit of the reference interval for plasma activity for each enzyme.

cific in one species will not always be so in others (Duncan et al. 1994a).

Biochemistry panels in veterinary medicine may include enzymes of skeletal muscle (creatinine kinase (CK), AST, ALT), hepatocellular (AST, ALT, SDH and GD) and pancreatic (AMY, LIP) origin as a means to assess damage to, or dysfunction of, these tissues in addition to data on electrolyte and metabolite concentrations (Kramer & Hoffmann 1997, Moss & Henderson 1999). Enzymes present in the kidneys and intestine are not generally found in the blood in vertebrates (Kramer & Hoffmann 1997, Moss & Henderson 1999). Instead, when these tissues are damaged, enzymes are believed to be released into the urinary space or intestinal lumen rather than into the circulation (Kramer & Hoffmann 1997). A similar situation is expected for the antennal gland and intestinal tissues in the lobster. When injury to the heart is suspected in vertebrates, the results of more specialized testing (e.g., isoenzyme determination) are combined with other clinical information to differentiate cardiac from general muscle injury because the enzyme composition of the tissues is very similar (Moss & Henderson 1999).

Overall, tissue enzyme activity in lobsters in this study resembled the distribution seen in other animals (Moss & Henderson 1999), with some exceptions. The low activity of GD recovered from the hepatopancreas was surprising because this mitochondrial

enzyme is central to ammonia metabolism and is known to be present in crustaceans (Claybrook 1983). An inhibitor may be responsible. GD activity could be detected in the isolated mitochondrial fraction, but not in homogenates, of the hepatopancreas in the crayfish (*Orconectes limosus*) (Claybrook 1983). A similar effect could account for the results obtained in this study. Plasma from apparently healthy lobsters often contains moderate levels of GD—presumably of muscle and/or hepatopancreatic origin.

AST and ALT are commonly used as indicators of hepatocellular injury in vertebrate species (Duncan et al. 1994a, Moss & Henderson 1999). Skeletal muscle injury is usually indicated by increases in CK and AST, but may also be accompanied by increased ALT in severe disease (Valentine et al. 1990, Kramer & Hoffmann 1997, Moss & Henderson 1999). For this reason, it is useful to have at least one enzyme that is considered tissue specific. CK, as a muscle-specific enzyme, serves this purpose in vertebrates (Kramer & Hoffman 1997, Moss & Henderson 1999). The equivalent enzyme in lobsters is arginine kinase (AK) (Horney et al. 2001). Unfortunately, neither an AK assay kit nor the reagents necessary for modifying the CK assay were available at the time of this study. Consequently, plasma AST and ALT activity in lobsters should be considered to be of either hepatopancreas or muscle origin.

SDH can be used as a specific indicator of hepatocellular injury

Figure 2. *Homarus americanus*, hepatopancreas. Hemocyte nodule in the intertubular space (IS). The nodule contains numerous cocci (*Aerococcus viridans*) in the center. The smaller group of cells at the upper right is a group of fixed phagocytes (P) with intracellular cocci. The hepatopancreatic epithelial cells (E) appear unaffected. The tubule lumen (L) is indicated.

(Duncan et al. 1994a, Moss & Henderson 1999). The relatively low SDH activities detected in multiple tissues in this study could indicate that either there is very little of this enzyme in these tissues, an inhibitor is present, or that the assay conditions (reaction temperature, substrate, etc.) were not optimal. Plasma SDH activity was often low or had poor repeatability. These findings suggest that SDH, under current assay conditions, may not be a useful enzyme for inclusion in lobster biochemistry panels. Further testing under different disease conditions will be required to confirm this.

Lipase is generally used as an indicator of pancreatic injury in vertebrates (Duncan et al. 1994b, Moss & Henderson 1999). Given the digestive function of the hepatopancreas, significant levels were expected in this organ as reported previously (Brockerhoff et al. 1967, Brockerhoff et al. 1970, Hoyle 1973, Biesiot & Capuzzo 1990). However, only relatively low activity was detected in the hepatopancreas with slightly higher activity in the proximal intestine in most lobsters in the current study. This discrepancy could be because of the different assay methodologies, or possibly an inhibitory substance. Differences in reporting enzyme activity among the studies make it impossible to compare the results. The presence of LIP activity in the intestinal preparations could indicate an additional location (i.e., enterocytes) for this enzyme or, incomplete removal of the lumen contents during sample preparation.

Detection of moderate levels of plasma LIP activity may be an indicator of recent feeding. Plasma LIP activities decreased while lobsters were held, fasted, at 2°C and increased when the animals were transferred to 15°C and fed. Refeeding after a period of starvation has been suggested as the cause of increased LIP activity in gastric fluid in *H. americanus* (Hoyle 1973). Plasma LIP activity decreased again in both groups as the trial progressed. Lobsters are reported to become inappetent shortly after infection with *A. viridans* (Stewart et al. 1972)—possibly a response to the inflammation associated with this disease. The branchitis may have caused a similar effect in the lobsters in the control group.

Unfortunately, food intake was not monitored closely enough in either group to confirm this hypothesis.

Amylase activity has been detected in hepatopancreas homogenates and gastric fluid in *H. americanus* (Wojtowicz & Brockerhoff 1972, Hoyle 1973, Biesiot & Capuzzo 1990). The hepatopancreas was the only tissue to consistently contain any significant AMY activity in this study. Because AMY activity was not detected in plasma samples from apparently healthy lobsters, this may indicate that plasma AMY will prove to be a sensitive and specific indicator of hepatopancreatic epithelial cell injury.

The reference intervals calculated for the two temperatures were quite similar, suggesting little effect of temperature. Whereas the intervals for male lobsters at 2°C to 4°C are likely an accurate reflection of lobsters in their natural surroundings, the intervals for 15°C may not be, because these lobsters were rapidly brought to this temperature under artificial conditions. Sampling lobsters that have gone through natural acclimation, with its attendant physiological adaptations, including possible induction of enzymes more suited to these higher temperatures, will be required to determine the validity of the current findings. Obtaining samples from a larger population of animals of both sexes at different molt stages from different fishing areas and during different seasons, is required to assess the possible effects of these variables.

Plasma is the preferred sample for measuring hemolymph enzyme activity. In the four animals tested, activities of ALT, AST and to a lesser degree, GD, were higher in serum than plasma. Activity of all three of these enzymes was found in the HLS. Thus, the serum activity is presumed to come from the hemocytes that lyse as part of the coagulation mechanism (Martin & Hose 1995). It is likely that the amount of enzyme contributed by the hemocytes will depend on both the total and differential hemocyte counts. A recent publication examined enzyme activity in hemolymph serum (Dove et al. 2005). It was noted that ALT and AST decreased in "warmer months," coincidental with absent hemolymph clotting. Poor clotting is frequently caused by hemocytopenia (Martin & Hose 1995)—the ALT and AST values obtained may have been an indirect indicator of the total and differential hemocyte counts rather than, or in addition to, release of these enzymes from tissues.

The benefits of using automated analyzers, with their internal standards and controls, include the relatively rapid determination of the activity of multiple enzymes in a small sample volume (~300 μL). Enzyme activity will be affected by reaction conditions such as substrate, temperature, and pH. For these reasons, reference intervals for enzyme activity are considered laboratory specific. In this study, all assays were performed at 37°C, the standard operating temperature of the automated chemistry analyzers and assay kits, although above the reported thermal tolerance (−1°C–30°C) of *H. americanus* (Lawton & Lavalli 1995). Previous work in homarid and panulirid lobsters and bivalves has detected enzyme activity when measured at 25°C and 37°C, with proteases of the spiny lobster demonstrating maximal activity at 50°C (Brockerhoff et al. 1970, Wojtowicz & Brockerhoff 1972, Hoyle 1973, Biesiot & Capuzzo 1990, Horney et al. 2001, Culloty et al. 2002, Celis-Guerrero et al. 2004, Gustafson et al. 2005).

Plasma enzyme activity appeared relatively stable when samples were refrigerated (2°C to 4°C) for up to 4 d or frozen at −20°C for 6 wk (results not presented). Stability studies were planned; unfortunately, only two samples with moderate enzyme activities were available for evaluation. The slight variations noted in these two samples may have been caused by the suboptimal

precision at these activity levels. Plasma AK had limited stability under different storage conditions and same day analysis was recommended (Horney et al. 2001).

Infection with *A. viridans* did not cause any consistent, specific, or clinically significant (>2–3× increase above upper limit of the reference interval) changes in plasma enzyme activity in this study to allow early detection of the *A. viridans* infection. The hepatopancreas is a major site of inflammation in gaffkemia, yet there was little evidence of damage to this tissue on the biochemistry panels (i.e., clinically significant increases in AMY, LIP, ALT, or AST activity). This may have occurred because the inflammation was primarily located in the connective tissues with relatively little involvement of the hepatopancreatic tubule epithelium, the presumed location of these enzymes. Increases in plasma enzyme activity may have been observed if the trial had progressed until the lobsters died of the infection when the inflammatory lesions would have been more severe.

Clinical enzymology is dynamic with hemolymph enzyme activity reflecting current conditions. Five lobsters had very high AST and ALT activity 2 d after arrival—the highest enzyme activities observed in this study. The most likely origin of these enzymes would be muscle and/or the hepatopancreas. The values in all five lobsters had decreased significantly by the next sample collection only 4 d later, suggesting a transient insult, possibly related to trauma and/or hypoxia experienced during shipping. Three of these five lobsters (1 control and 2 treatment) showed progressive increases in GD accompanied by mild increases in AST and/or ALT during the gaffkemia trial. Whether the increase in GD was related to the previously elevated AST and ALT, or to some underlying process exacerbated by the *A. viridans* infection, remains speculative. There were no gross or histological lesions

unique to any of these five lobsters at necropsy to account for the enzyme changes.

CONCLUSIONS

This study has identified the tissue distribution and established plasma reference intervals in *H. americanus* for ALT, AST, GD, AMY, LIP and SDH. This information can be used as a starting point to assess the usefulness of clinical enzymology for the diagnosis of disease in *H. americanus*. More information on the stability of these enzymes under different storage conditions, factors that can affect their circulating half life, possible induction and effects of the molt cycle on plasma activity, is needed. Plasma enzyme activities are most likely a tool to be used in research settings at present. Although plasma enzyme activity did not prove to be a sensitive test for detecting gaffkemia, with further investigation one or more enzymes may be identified that can be used to assess the general health of lobsters upon arrival at pounds (e.g., screening for the presence of underlying diseases) or detecting the effects of rough handling during transport, which might affect survivability under long-term holding conditions. This information could be useful when making marketing and management decisions.

COMPARISON OF EARLY SEASON VERSUS LATE SEASON TRAP SCHEDULES FOR HARVEST OF RED SWAMP CRAWFISH *PROCAMBARUS CLARKII* CULTURED IN EARTHEN PONDS WITHOUT PLANTED FORAGE

CORTNEY L. OHS¹ AND LOUIS R. D'ABRAMO²

¹University of Florida Institute of Food and Agricultural Sciences Indian River Research and Education Center 2199 South Rock Road Fort Pierce, FL 32945; ²Mississippi State University Department of Wildlife and Fisheries Box 9690 Mississippi State, Mississippi 39762

ABSTRACT The effect of a redistribution of the majority of total trap harvest days (69) during April through October on yield of red swamp crawfish *Procambarus clarkii* cultured in earthen ponds without planted forage was evaluated in northeast Mississippi, USA (Latitude 33.45 and Longitude 88.82). The majority of trap days occurred from either April through June (55.1%), early harvest schedule, or July through October (62.3%), late harvest schedule. Twelve ponds (0.04–0.05 ha), 6 replicates per trap harvest strategy, that already contained established populations were provided a pelleted feed during 10 mo and trap harvested according to a common protocol except for the different monthly schedules. For the early and late harvest schedule treatments, mean total production (2448 and 2269 kg/ha), mean number harvested per ha (105,770 and 104,411/ha), and mean individual harvest weight (23.6 and 22.1 g) were not significantly different. These results suggest that the majority of trap harvesting in ponds without planted forage can occur after trap harvest in forage based culture ponds and natural habitats is usually terminated. When traditional supply is low, price and demand can be high in certain markets. This successful shift in harvest days introduces flexibility in management strategies that could be critical to the financial success of an enterprise based on production of crawfish in ponds without planted forage.

KEY WORDS: red swamp crawfish, *Procambarus clarkii*, crawfish aquaculture in deep earthen ponds

INTRODUCTION

Previous research has been conducted on red swamp crawfish, *Procambarus clarkii*, cultured in earthen ponds without planted forage to evaluate feasibility (D'Abramo & Niquette 1991), initial stocking densities (D'Abramo et al. 2003), harvesting schedules (D'Abramo et al. 2003) and addition of substrate to culture ponds (D'Abramo et al. 2006). A summary of these results and the suggested management strategies are summarized in D'Abramo et al. (2002) and D'Abramo et al. (2004). Trap harvesting in traditional or forage-based crawfish production ponds in Louisiana commonly occurs from December through May. Ponds are usually drained in either May or June, and pond bottoms are then dried and planted with an agricultural crop such as rice or sorghum. Ponds can be drained as early as February or as late as August and this management decision is based on economic considerations. Extended harvests in forage-based ponds more likely occur at comparatively higher latitudes. The crawfish harvest season in Louisiana natural fisheries, centered in the Achafalyan Basin, can extend the availability of crawfish into June depending on the amount of rainfall, water level and subsequent boat accessibility within the basin (Huner 1997). Eversole (1988) evaluated two trap harvesting schedules in forage-based ponds in South Carolina and despite a significant reduction in forage present, similar production was achieved by utilizing a trap schedule that occurred from April to May or extended through June.

June through October is when crawfish are not typically available and price and demand can be high in certain markets. Utilization of this trapping schedule could provide a producer the ability to extend product availability and provide the opportunity to maximize profit by avoiding harvesting and marketing during periods of high supply and low price.

The objective of this experiment was to evaluate the effect of two trapping schedules with different temporal arrangements of

trap days on total production, the number of crawfish harvested per ha and the mean individual weight of harvested crawfish in earthen ponds without planted forage.

MATERIALS AND METHODS

Experimental Treatments and Ponds

There were two experimental treatments, early and late season, referring to when the proportionately higher level of trapping occurred during a 7-mo period of April 1 to October 24. A total of 69 trap days occurred for each of the two treatments. For the early season treatment, 55.1% of the trap days occurred during April through June, whereas for the late season, 62.3% of the trap days occurred from July through October (Fig. 1). Each treatment was randomly assigned to six replicate ponds.

A total of 12 freshwater earthen ponds ranging from 0.04–0.053 ha in surface area and a mean depth of 1.2 m were used. The ponds were rectangular shape, between 1.5 and 1.8 m at the deepest point. Ponds were stocked 4 or 5 y before the initiation of this experiment and the resident population of crawfish originated from natural recruitment. All ponds had been in continuous production for 4 or 5 y and had been previously used for experiments investigating various management strategies for the production of red swamp crawfish without planted forage.

Vertically suspended within the water column and below the water surface of all the experimental ponds was a substrate consisting of orange, plastic safety barrier fencing (30.5 m length and 1.2 m height). The area of substrate in each pond was equivalent to 50% of the bottom surface area of the pond and was estimated by assuming it was a one-sided solid sheet (36.6 m²). The substrate was attached to 1.5 m steel reinforcement bars (four bars per 30.5 m length of substrate) with twine (D'Abramo et al. 2006) and had been in the ponds continuously for three years of growth, harvest and recruitment of crawfish populations associated with previous experiments.

Figure 1. The number of trap days each month from April to October for the early and late season harvest experimental treatments.

Feed

A 32% crude protein, sinking, formulated feed manufactured by pelletization (Producers Feed Company, Isola, MS) was added to the experimental crawfish ponds during the entire calendar year. The feed is considered to serve principally as an indirect organic fertilizer rather than a direct source of nutrition, serving to stimulate the rates of natural productivity in the ponds. The total amount of feed provided to each pond during the 12-mo period prior to and during the harvest of crawfish was 6,750 kg/ha. Monthly feeding rates were based on the estimated resident biomass of crawfish and water temperature (Table 1) and followed recommendations of D'Abramo et al. (2002).

Harvesting

Three funnel (3.8 cm inner diameter entrance) pyramid traps constructed with hexagonal wire mesh (1.9 cm diameter openings) (Gulf Coast Wire Products, Kaplan, LA) were used and positioned along the perimeter of each pond at a density of 81/ha. The traps had necks that extended above the water surface and were longer (60 cm) than the necks of traditional pyramidal traps to accommodate the greater depth characteristic of ponds without planted forage. At the top of the necks, polyvinyl chloride (PVC) retaining rings (9 cm height) were located to prevent escape of crawfish

through the top of the trap. Each time a trap was baited, approximately 100 g of artificial bait (Gros Rouge Crawfish Bait, Cargill, Minneapolis, MN) was added.

Trap days were scheduled differently for each treatment to achieve the necessary number of trap days designated for each month (Fig. 1). Traps were harvested on Monday, Tuesday, Thursday and Friday; or Tuesday, Thursday and Friday; or Thursday and Friday or Friday only to accommodate the necessary number of trap days assigned per month. Soak times for the traps were either 24 or 48 h depending on the number of trap days per week. If the next scheduled trap day was more than 48 h in the future, traps were inverted and reset 24 h prior to the next scheduled harvest. Trapping protocol based on water temperature, as described by D'Abramo and Ohs (2003), was followed. When trapping occurred during warm water conditions ($>19^{\circ}\text{C}$), bait was included in the traps. At temperatures between 15°C and 19°C , traps were not baited and allowed to soak so crawfish could passively move into the traps, possibly seeking refuge. For each harvest day, the total number and total weight of crawfish harvested from each pond were determined and recorded.

Water Quality

Water temperature of the ponds was recorded twice daily, and dissolved oxygen was recorded twice daily except during June through September when it was measured three or more times per day. When the dissolved oxygen concentration was anticipated to decrease below 5 ppm, aeration was provided to the ponds by a 0.5 hp aerator (Aerolator Corp., Kansas City, MO). Additional, emergency aeration was provided by a tractor driven paddlewheel when the dissolved oxygen concentration decreased below 3 ppm. Every third day, from May through August, pH was measured and recorded at approximately 13:00. All ponds were treated with gypsum at approximately 181.6 kg/ha in June as a prophylactic treatment to minimize the potential for potentially lethal alkaline pHs to occur.

Statistics

A one-way analysis of variance (ANOVA) was used to determine if differences existed between treatments for mean production (kg/ha), number of crawfish harvested (number/ha) and overall mean individual weight (g) (SAS 1988). Differences were considered significant at $P \leq 0.05$.

RESULTS

There were no significant differences between treatments in mean total production ($P = 0.48$), mean number harvested per ha ($P = 0.93$), or mean individual weight of harvested crawfish ($P = 0.19$) (Table 2).

TABLE 1.

Monthly and annual number of days and amount of feed provided to each of the experimental ponds.

	kg/ha	% of Total	Days/Month
January	0	0	0
February	0	0	0
March	0	0	0
April	1744	20.5	30
May	1097	17.4	31
June	1041	16.5	30
July	788	12.5	31
August	506	8.1	31
September	450	7.1	30
October	506	8.1	31
November	422	6.7	30
December	197	3.1	15
Total	6750	100.0	259

TABLE 2.

Mean total production, mean number harvested, and mean individual weight of crawfish harvested from experimental earthen ponds according to early and late season harvest treatments.

Treatment	Mean Total Production (kg/ha)	Mean Number Harvested (number/ha)	Mean Individual Wt. (g)
Early season	2448 \pm 160	105,770 \pm 9296	23.6 \pm 0.69
Late season	2269 \pm 185	104,411 \pm 10,915	22.1 \pm 0.83

The 20.3% increase in the number of trap days that occurred in June through October for the late season treatment resulted in a corresponding 16.5% increase in total production and a 15.3% increase in the number of crawfish harvested during this same period. Accordingly, by assigning more trap days later in the harvest season (June through October) the total amount of crawfish harvested increases by approximately 375 kg/ha. Monthly trap days, harvest yield (kg/ha) and number harvested/ha, expressed as a percentage of the total, are presented in Table 3.

DISCUSSION

The results of this investigation provide insight into the true seasonality of crawfish production at the latitude where the study occurred. Obtaining this information is only possible through the use of a management practice that does not include planted forage. By utilizing the management strategies in the present experiment, it seems that production of 2200–2500 kg/ha/year can be perpetually achieved in properly managed 0.5 ha earthen ponds during a 7 mo period with 69 trap days, regardless of which of the present study's trapping schedules is followed. Recently initial attempts to incorporate this method of crawfish production into one 0.81 ha pond produced harvested annual yields slightly less (~2000 kg/ha) than what has been achieved in the experimental ponds. Farmers who use earthen ponds without planted forage do have the option of these two management strategies for harvest.

In the current study, only 20.3% of the trap days were shifted from April and May to June through October. Previous research has shown that trap days can extend over a 12-mo period during some years with a possible exception of January and February, typically the coldest months of the year (D'Abramo et al. 2003). Therefore, it may be possible to shift more trap days to later in the year with a corresponding reduction in trap days in March. Nonetheless, sufficient trapping effort should most likely be maintained during April and May when the resident biomass of crawfish is highest. This strategy of continued removal by harvest should reduce the possibility of decreased growth and production, which could occur if high population densities are allowed to persist for prolonged periods. In addition, an appropriate level of harvesting of the resident population probably contributes to reductions in cannibalism and emigration.

The maximum trapping effort that can be imposed without altering the rate of natural recruitment is not known. Mean indi-

vidual weight data collection over many years of experiments have shown that in a typical 0.05 ha research pond, a reduction in mean individual size does not occur until more than 100 trap days per year are extended over 10 mo (D'Abramo et al. 2003).

It may be possible to maintain the same trapping effort during periods of the highest population density and further increase the number of trap days to the later portion of the harvest season. This strategy may further increase total production and potential profit, whereas not reducing the resident population to a level whereby natural recruitment for harvest during the following year is adversely affected.

Wholesale prices for crawfish vary from month to month. Mean monthly wholesale prices in Louisiana are \$3.85 per kg in November and decrease to \$1.32 per kg in June (Romaine et al. 2005). In Louisiana, the lack of a cultured or captured product from July to October means a wholesale price does not exist. If available from July to October in Louisiana, the product may not likely command the November price of \$3.85 per kg because of lower demand caused by a large supply of other readily available seafood such as crabs and shrimp. The application of wholesale prices of crawfish in Louisiana to markets outside of Louisiana is difficult because 90% of the crawfish produced there are consumed locally (Romaine et al. 2005).

As part of the economic analysis in a previous publication on nonforage-based crawfish production systems (D'Abramo et al. 2002), a mean price of \$3.31 per kg was used for the entire year. This is likely a conservative estimate from July through October, but is a good price estimate throughout the entire year in markets outside of Louisiana. Another notable difference between Louisiana markets and markets outside the region is the marketing chain and the various steps involved from producer to consumer in Louisiana (Romaine et al. 2005). These multiple steps to reach the consumer spread revenue to businesses in the various steps whereas in other regions the producer may receive a higher price because they market directly to the consumer or to a single wholesaler prior to the product reaching the consumer. Similar or higher selling prices could also be obtained by capitalizing on a seasonally based sale of crawfish as fish bait.

In the present study, utilizing the late season trapping schedule and shifting 20.3% of trap days from April and May to June through October increased production during the same time period by 16.5%. The critical information from this study for a producer is that there is no significant difference in production between the two trap schedules. A late season trap schedule can extend availability of product to later in the year during periods when prices may be higher, depending on local demand and the marketing effort of the producer. This could increase annual gross receipts and the potential profit of a nonforage based earthen pond crawfish production operation.

ACKNOWLEDGMENTS

The authors thank the staff of the Eastern Unit of the National Warmwater Aquaculture Unit for their assistance in the management of the water quality of the experimental ponds, the distribution of feed to the ponds, and the harvest of crawfish. The research was supported by the United States Department of Agriculture through a special grant for aquaculture research, and approved by the UF/IFAS Indian River REC for publication as Journal Series Number R-020606.

A PERSPECTIVE ON ECOLOGICAL CONSIDERATIONS IN CRAWFISH POND AQUACULTURE

JAY V. HUNER

Crawfish Research Center, University of Louisiana at Lafayette, Lafayette, LA 70504

ABSTRACT The suite of resident, migrant, breeding, and wintering waterbirds depending on this region includes grebes, pelicans, cormorants, anhingas, wading birds, waterfowl, coots, rails, gallinules, shorebirds, gulls, and terns. All taxa now use the artificial freshwater wetland habitat provided by the ag wetlands. These taxa include local, regional, continental and hemispherical populations. Crawfish ponds are especially valuable cool season habitat for predaceous waterbirds because they provide shallow water systems rich in invertebrate and small vertebrate prey during the period from midautumn through midspring when most ricefields are drained. Numerous other bird species use riparian areas around ag wetlands either as residents or seasonal visitors. Over 280 bird species have been identified in and around crawfish-rice systems in Louisiana. Whereas birds are conspicuous species associated with ag wetlands, numerous other vertebrate species including mammals, reptiles and turtles use the habitat. In addition, fishes in waterways receiving pond effluents receive significant food resources when water is released from the ponds.

KEY WORDS: crawfish, aquaculture, ecological services, ag wetland habitat

INTRODUCTION

Freshwater crawfish, *Procambarus* spp., are cultivated in shallow-water impoundments by establishing self-perpetuating populations in permanent culture systems or mature crawfish in rotational culture systems (McClain & Romaine 2004). Most crawfish culture is located in Louisiana where 52,000 ha are devoted to crawfish production (LCES 2004). Most of the shallow-water impoundments are used to cultivate rice in warm months and are reflooded for crawfish culture in the cool months following rice harvest. These so-called agricultural (ag) wetlands are managed in such a way to follow the region's natural wetland cycle with alternate wet dry cycles. Crawfish mature in 4–6 mo and retreat to burrows during the heat of the summer when natural wetlands are either dry or water is too hot for survival and growth of the crawfish. The two important species are the red swamp crawfish, *Procambarus clarkii* and the white river crawfish, *Procambarus zonalungulus*, whose basic biology and size are similar. See McClain and Romaine (2004), Huner (2002a) and Avery and Lorio (1999) for information about basic crawfish biology and fisheries and aquaculture management considerations.

Because crawfish are cultivated by simulating natural hydrological cycles in what amounts to be seasonally flooded wetlands, it should not be surprising that crawfish ponds provide ancillary ecological services (Huner 2002b). Furthermore, crawfish culture, as practiced with *Procambarus* spp. is probably the most sustainable form of pond aquaculture practiced in North America. That is, agricultural waste, rice stubble serves as the base of the food web that generates substantial crops of crawfish with minimal environmental impacts while providing economic benefits to communities (Huner 2002b, Caffey et al. 1996). This brief review discusses the various ecological services, foremost being waterbird habitat, provided by the agricultural community through cultivation of crawfish in shallow water, earthen ponds.

WATERBIRD HABITAT

Huner et al. (2002) discuss at length the management of agricultural wetlands in the coastal regions of Louisiana, which ultimately benefit resident and migrating waterbirds. Over 280 bird

species including at least 75 waterbird species have been documented utilizing agricultural wetlands and adjacent riparian areas. This discussion is appropriate, however, for the South in general. Rice and crawfish farming operations are the main agricultural wetlands found in Louisiana. The following are water management practices associated with permanent and rotational crawfish ponds:

Permanent Crawfish Ponds

These systems produce crawfish on a continuing basis. When rice is planted as a forage base for crawfish in permanent ponds, grain is usually not harvested. Where rice is harvested, such systems are considered to be a type of rotational management—see later. Alternatives to rice as forage bases most commonly encountered include sorghum-sudan grass hybrid or volunteer vegetation including perennial forbs such as alligator weed, *Alternanthera philoxeroides*, smartweeds, *Polygonum* spp., duck potatoes, *Sagittaria* spp. and annual wetland grasses and sedges. These ponds are usually “open” in the sense that they are not wooded. However, there is some acreage associated with impounded forested wetlands (swamps). These so-called swamp ponds are usually very large compared with most ponds, regardless of type, that rarely exceed 20 ha in size. They typically have very poor crawfish production compared with all other crawfish pond systems.

Rotational Crawfish Ponds

In general, these systems produce crawfish in alternate years. However, some farmers harvest rice and crawfish from the same ponds year after year and are rarely restocked with crawfish after the first crawfish crop is harvested. In most rotational ponds, crawfish are stocked after the planting of rice and the establishment of a shallow “flood” of water once the rice has developed permanent leaves. Rice is managed for grain production and harvested. After rice harvest, the ponds are refilled in the fall and managed for crawfish production into the following spring. Once crawfish harvesting ceases, farmers may drain the fields and plant a crop such as soybeans or leave the fields fallow until rice is planted the following spring. Crawfish are then stocked and the cycle is repeated. If a crop like soybeans is not planted, farmers often choose to not drain fields until the following autumn to control weeds. They do not add water to the fields and water is lost to evaporation and percolation with rate being related to rainfall patterns. (See

McClain & Romaine 2004, McClain 2005 and Romaine 2005 for more information about management of permanent and rotational crawfish pond systems.)

Bird Feeding Niches and Behaviors

The presence of water in the crawfish ponds provides feeding habitat and loafing habitat for all types of waterbirds including waterfowl, grebes, pelicans, cormorants, wading birds, shorebirds, coots, rails, gulls and terns. Furthermore, adjacent riparian areas and nearby wetlands attract numerous nonwaterbird species (Huner & Musumeche 1999, Musumeche et al. 2002). Each suite of birds has a particular feeding niche. Waterfowl and coots feed largely on rice left in the fields intentionally (permanent ponds) or as a consequence of harvesting processes (rotational ponds). They also benefit from seeds, green plant materials and tubers associated with volunteer vegetation especially where that is the crawfish forage base. Ducks (and coots) will also prey on zooplankton "blooms" concentrated along shorelines by winds especially in the spring and benthic invertebrates including crawfish when animal protein is required for egg formation. Wading birds and rails feed along pond margins when water is deep or throughout shallow areas present as ponds are filled or drained or because of untended water loss from evaporation or seepage. Hovering birds such as gulls and terns take prey from the water surface. These birds are especially adept at gleaning molting crawfish from emergent vegetation where they concentrate during daylight hours. Soft crawfish have very low mineral content and, being soft, are very easy to eat. Diving birds such as grebes and cormorants feed within the water column often in water so shallow that they cannot submerge. Pelicans, specifically American White Pelicans, form feeding lines and drive prey, including crawfish, toward shores where they are concentrated and easily scooped up. Shorebirds feed wherever shallow water is available—see later.

With the exception of shorebirds, all other species use crawfish traps that extend above the surface for resting places. Cormorants and wading birds are often seen to remove cut fish from traps when it is used for bait. Cormorants, wading birds and gulls regularly take crawfish that climb to the water surface inside and outside of traps.

There is no set time that ponds are drained and flooded. Because target flooding and draining dates are midOctober and mid-June (Avery & Lorio 1999), management considerations generate wide windows of flooding dates from midsummer to midfall and draining dates from early spring to late summer. Food organisms are most abundant when ponds are drained. Draining can take place as early as February or March even if the crawfish crop is too poor to justify harvesting, but, even though the crops are not worth harvesting, prey concentrates to desirable levels as water levels drop generating excellent feeding opportunities for carnivorous birds. In rotational rice-crawfish ponds, draining may be delayed until midfall to control weed growth prior to preparing soils for planting spring rice crops. The moist soils that are ultimately exposed are of special significance to shorebirds including wintering species or migrants. Such soils are sources of high densities of invertebrate prey especially insect larvae, crustaceans and annelid worms that provide the mainstay of shorebird diets.

Table 1 provides general information on the seasonal utilization of crawfish pond systems by waterbirds. See Huner et al. (2002) for more details.

In the case of rotational crawfish ponds, a practice that is es-

TABLE 1.

Seasonal abundance of major waterbird taxa in crawfish pond systems in southern Louisiana (USA).

Taxon	Season			
	SP	SU	F	W
Ducks	C	R	C	C
Grebes	R	U	U	R
Pelicans	—	—	—	R
Anbingas	R	R	R	—
Cormorants	U	C	C	U
Bitterns	R	R	R	R

Night-herons	U	C	C	U
White ibises	A	C	A	A
Dark ibises	A	C	A	A
Spoonbills	U	U	C	U
Storks	—	U	U	—
Coots	U	X	—	C
Shorebirds	C	U	A	U
Gulls	C	U	U	A
Terns	U	R	U	U

Legend. Seasons: SP = spring, March to May; SU = summer, June to July; F = fall, August–October; and W = winter, November to February. Seasonal abundance: A = abundant, widespread and easily found in proper habitat in large numbers; C = common, widespread and easily found in proper habitat, but generally not in large numbers; U = uncommon, widespread and present, but in low numbers at proper season; R = rare, found infrequently at proper season, but a general pattern of occurrence is evident.

pecially important to waterbirds involves leaving water in the pond once crawfish harvesting ceases. Water is not drained but allowed to evaporate. Because the bottoms of most of these ponds have been leveled carefully with laser technology, there is very little slope and variation in depth. Water remains across most of the pond bottom until it finally dries or it is drained to permit tillage for an agronomic crop the following spring. The presence of water reduces problems with terrestrial weeds when pond bottoms are tilled. In practice, water depths of 2.5–5.0 cm generate ideal habitat for shorebirds migrating through the area during the "fall" migration beginning in July and ending the following October. Likewise, large concentrations of post nesting wading birds frequent these sites and good numbers of early fall waterfowl such as Blue-winged Teal, Northern Shoveler and Northern Pintail are attracted to this shallow water/moist soil habitat.

Wetland Habitat Considerations

Rice and/or crawfish are cultivated in over 300,000 ha of shallow earthen impoundments within 160 km of the Gulf of Mexico from the central Texas coast eastward to southeastern Louisiana. The region includes the Gulf Coastal Plain and the Lower Mississippi River Valley. Annual loss of 4,475 ha of coastal wetlands over the past 50 y has significantly reduced desirable natural freshwater habitat in the region (Coreil 1993, Raynie & Beasley 2000).

The significance of agricultural wetlands as waterbird habitat becomes very clear when one notes that over 600,000 ha of adjacent coastal wetlands have disappeared since the 1950s (Coreil 1993, Raynie & Beasley 2000). What was once ideal waterbird habitat has become open water with no chance that it will be

restored in the foreseeable future. Therefore, "artificial" wetland habitat has replaced those lost wetlands.

Landscape Considerations

Crawfish are cultivated mainly in two distinct geographical regions in Louisiana—coastal prairie areas with light, loessal soils and floodplain areas with heavy, alluvial soils (Huner 2004a, 2004b). An impervious "hard pan" develops in cultivated prairie areas under several centimeters of topsoil and holds the water permitting the cultivation of rice and crawfish. The heavy clays in floodplain areas naturally hold water tenaciously and permit rice and crawfish culture. Interestingly, much of the area where crawfish is cultivated in floodplains was very low, flood prone, marginal land cleared in the 1960s to permit cultivation of soybeans. Within 5–10 y soybean cultivation became unprofitable and, at least in southern Louisiana, such fields surrounded by levees for flood control, were converted to crawfish ponds.

During the drought period of 1999 to 2001, there was a very real reduction in crawfish yields in the prairie regions of Louisiana, whereas crawfish yields in alluvial regions did not suffer as much (Huner 2004a, 2004b). To be sure, Icon, a systemic rice pesticide, was associated with considerable loss of crawfish in prairie regions. However, scrutiny of crawfish production from alluvial areas, especially where treated rice was not used, suggests strongly that drought resulted in a much greater reduction of crawfish production in the lighter prairie soils than in alluvial soils. Therefore, it is apparent that farmers need to manage soil moisture much more carefully in the prairie soils than the alluvial soils. This, then, benefits waterbirds as there is more moist soil/shallow water habitat available to them.

Threats to Waterbird Habitat Provided by Ag Wetlands

Farmers will cultivate rice and/or crawfish only as long as it is economically feasible to do so (Huner et al. 2002, Westra et al. 2005). Rice farming would not exist today were it not for farm subsidies. Crawfish was once considered to be a providential "cash" crop. Today, it is a principal source of income in a very troubled agricultural economy (McClain 2005). If crawfish, for whatever reason, fails to sustain the rice component of an integrated rice-crawfish enterprise then the enterprise will close and the wetland habitat will not be sustained. Farmers have been evaluating sugar cane as an alternative to rice in southwestern Louisiana. Sugar cane must be kept reasonably dry so cane fields lose shallow water/moist soil functions when a rice crop is replaced with a sugar cane crop.

In the case of absentee landowners, farmers leasing rice fields cease to farm rice if the practice based on rice values and lease costs exceed income. Fields are abandoned and are quickly overgrown by exotic tallow trees that form thick, impassable stands of trees in less than 5 y. The costs of clearing such trees are such that such properties are unsalvageable in the current agricultural economy.

Farmers are generally of the opinion that predaceous waterbirds negatively impact their crawfish crops. This issue is discussed at length by Huner et al. (2002). In the absence of replicated, controlled predation studies, ancillary observations suggest that birds such as wading birds, gulls, terns and pelicans probably do not negatively impact crawfish production directly when farmers practice recommended management procedures. However, larger birds using crawfish traps as perches do dislodge them causing loss of

bait and catch and, in that case, do have a negative impact on the crawfish operation. Waterbirds largely considered to be nonpredaceous, such as geese and coots, can adversely impact crawfish production indirectly by destroying emergent vegetation, especially rice stubble. Aside from providing fuel for the detrital system, the emergent vegetation serves as critical substrate for crawfish dispersal, provides access to the surface and atmospheric oxygen when dissolved oxygen levels are very low and cover from the myriad of predators, including birds, associated with all wetlands, natural or artificial, in the region.

Use of water, especially ground water, by farmers for irrigation of all crops is being carefully scrutinized as demands for water escalate for industrial and residential activities (Lutz et al. 2004, Huner et al. 2002, Lovelace 1994). In 2000 (DOTD 2002), Louisiana "rice" farmers used approximately 42% of the ground water used in the state. Increases in the cost of "energy" force farmers to be much more guarded in their use of water, regardless of source, because they must pay for the energy required to pump the water into pond systems. However, farmers will continue to use a very high percentage of the water consumed in Louisiana.

If resource managers do not recognize the critical wetland habitat created by rice and crawfish farmers, they could make water allocations that negatively impact waterbird populations with staggering implications especially when hemispherical shorebird populations are taken into account.

OTHER ECOLOGICAL/SOCIETAL SERVICES

All impounded agricultural areas hold water for varying lengths of time following rainfall events. Water levels in rice and crawfish systems are rarely held at drain level so all units have some freeboard that equates to water storage capacity (Huner 2002b). However, because drains cannot accommodate the volume of water falling into ponds during major rainfall events, ponds store the water for varying periods of time until the drains can discharge water temporarily stored in the ponds. Even empty ponds hold water until such time as it can drain through the openings cut in levees. As a result, rice fields and crawfish ponds hold water and reduce the impact of floods in lower reaches of receiving bayous, streams, and rivers, a definite benefit to homes and businesses. Furthermore, even when such locations drain completely, soils remain damp for various lengths of time creating landscape level moist soil vistas. There are at least 240,000 ha of land used for rice production and surrounded by levees in Louisiana during nonrice production seasons (LCES 2004). No more than 20% to 25% of this land is flooded for crawfish production then.

Water is discharged from crawfish ponds for aeration purposes, to eliminate excess rainwater, and to drain ponds during the spring and summer (Lutz et al. 2004, Huner et al. 2002, Lovelace 1994). Concerns about discharge of pollutants, especially nutrients and suspended solids have been addressed by the development of Best Management Practices (BMPs) (Lutz et al. 2004). In general, water quality is not generally so poor as to cause excessive concern as long as the BMPs are followed (Parr et al. 2004).

The waters discharged from crawfish ponds benefit the receiving waters in 2 ways (Huner 2002b). First, water is often discharged during very dry periods in the mid-late fall and late spring/early summer when receiving waters exhibit seasonally poor water quality. Therefore, the increase in volume and movement of water generated by discharges actually, it can be argued, improve water quality. Second, fish food organisms are discharged

with effluent providing feeding opportunities for fish and other predaceous aquatic organisms comparable, it can also be argued, to discharges from natural wetlands.

CONCLUSIONS

Crawfish culture, as practiced in the southern USA, represents a form of highly sustainable aquaculture that has very real benefits to wildlife and fisheries resources. Crawfish impoundments are artificial wetlands, comparable in many ways to natural wetlands in the region. Resources managers should encourage crawfish aquaculture wherever it is economically feasible and seriously consider managing wetlands on state and national wildlife management properties in a similar manner.

Incorporation of crawfish management into government-sponsored land conservation programs should encourage landown-

ers to sustain standing water habitat outside of program mandated fill/drain requirements. Farmers could adjust the times when their ponds are filled or drained to maximize benefits to many species, especially migrating shorebirds. The issue of possible damage done to crawfish crops by predaceous birds remains unresolved but, if such birds are proven to be deleterious, compensation to encourage farmers to continue to cultivate crawfish would certainly be justified on the basis of the ecological value of their ponds to wildlife.

EMBRYO DEVELOPMENT AND MORPHOMETRY IN THE BLUE KING CRAB *PARALITHODES PLATYPUS* STUDIED BY USING IMAGE AND CLUSTER ANALYSIS

BRADLEY G. STEVENS

National Marine Fisheries Service, P.O. Box 1638, Kodiak, Alaska, 99615

ABSTRACT In this paper the embryonic development of laboratory-reared blue king crab, *Paralithodes platypus*, from the Pribilof Islands in the eastern Bering Sea is described. Developing embryos were removed from a female crab at various intervals, digitally photographed under a compound microscope and analyzed using Image-Pro Plus. Nine morphometric parameters were used, including seven measurements (total area, yolk area, embryo length and width, average diameter, eye length and width) and two calculated indices (percent yolk and elongation). First cell division was not apparent until day 4, after which divisions occurred daily until the blastopore appeared at day 28. A “V”-shaped embryo became apparent on day 114, followed by rapid appendage development. The eyes became pigmented by day 192. Hatching occurred from day 381 to day 409, and required at least 33 d to complete. Embryo area declined from an initial value of 0.95 mm² on day 1–0.83 mm² on day 72 and then increased to 1.28 mm² on day 388. Growth of all characters reached a plateau between days 240 and 353, and then increased rapidly until the middle of hatching (day 390). Visual examination was better at defining early changes, but cluster analysis of morphometric measurements was a better technique for defining middle and later stages. Both techniques resulted in an optimum selection of 12 developmental stages. Embryonic development has been described for few decapod crustaceans, and no standard exists for defining developmental stages. Multivariate analysis of morphometric measurements may lead to improved understanding of crustacean embryogenesis, allow standardization of staging and enable studies of environmental influence on development. The technique also has applications in the aquaculture industry.

KEY WORDS: king crab, development, hatching, incubation, embryo, morphometry, image analysis

INTRODUCTION

Studies of crustacean population fluctuations must include techniques for assessing environmental impacts such as climate change on reproduction, including embryonic development rates, diapause and irregular embryogenesis. Previous studies of embryo development in decapods have relied on traditional visual techniques to define developmental stages (Moriyasu & Lanteigne 1998, Yamaguchi 2001). However, the subjective nature of these methods leads to high variability because of the lack of standardized techniques or equipment, and such studies can rarely be applied to other species. Recent developments in digital imaging equipment and software have made it possible to improve the quality and reliability of morphological assessments in human and veterinary medicine. Image-analysis techniques have been used successfully to assess sperm morphology and quality in humans (Verstegen et al. 2002), horses (Hidalgo et al. 2005), fish (Gage et al. 2002), and marine mammals (Kita et al. 2001), and these techniques are easily adapted to studies of embryos as well. Crustaceans are particularly suitable research subjects because of their external and easily accessible embryos. Morphometry of embryos has been used to describe developmental stages in the freshwater prawn *Macrobrachium borellii* (Lavarias et al. 2002).

King crabs are large anomurans that are commercially exploited in many parts of the world. Commercially valuable species include red and blue king crab *Paralithodes camtschaticus* (Tilesius, 1815) and *P. platypus* Brandt, 1850, respectively, golden king crab *Lithodes aequispinus* Benedict, 1894, scarlet king crab *L. couesi* Benedict, 1894, European king crab *L. maja*, southern king crab *L. santolla* and others. Despite their value, embryonic development has only been studied for red king crab in Japan (Nakanishi 1987). There is no standardized scheme for describing devel-

opmental stages for king crab or any other large decapod crustacean.

Blue king crab (BKC) have historically supported lucrative fisheries in the eastern Bering Sea (EBS) at St. Matthew Island and near the Pribilof Islands (St. Paul and St. George). In 1999, both populations declined drastically, and their fisheries were closed, leading to renewed interest in research on their biology. Blue king crab have a 2-y reproductive cycle; in the first year of this cycle (the spawning year), female crabs molt, extrude eggs, mate and carry the developing fertilized embryos for approximately 1 y (Somerton & MacIntosh 1983, Jensen et al. 1985, Somerton & MacIntosh 1985, Jensen & Armstrong 1989). During the second (or hatching) year, larvae are released, but the crabs do not molt or mate again (Stevens in press), unlike female red king crabs that hatch, molt, mate and extrude annually (Stevens & Swiney, in press).

This research was undertaken as part of a larger study on the early life history of BKC, including development of cultivation techniques to ensure a supply of small crab for future research (Stevens et al., in press). This article describes the embryonic development of BKC during cultivation in the laboratory and methods to standardize definitions of developmental stages using visual as well as morphometric characteristics.

MATERIALS AND METHODS

Blue king crabs were captured by trawl about 20 miles northeast of St. Paul Island, in the eastern Bering Sea, during October 2003 (for dates and locations see Stevens in press). Crabs were kept in recirculating seawater aboard ship for several days until returning to Dutch Harbor, Alaska. They were then packed in insulated coolers between layers of wet burlap, kept chilled with frozen ice packs and shipped by air to Kodiak, Alaska. Upon arriving in Kodiak, crabs were placed in a 2500-L tank containing chilled (4°C) seawater. Most female crabs were new-shelled and ovigerous, but two female crabs had old shells and empty egg cases, evidence that they had released larvae the previous spring.

When one of the old-shell crabs subsequently molted, it was

Corresponding author. E-mail: bradley.g.stevens@noaa.gov

placed in a tank with a male crab and observed daily during grasping until new clutches of eggs were extruded and the female was released. Examination of embryos began 1 d after fertilization (day 1). A small cluster of 50–100 eggs was removed every other day for the first 3 wk and at 2–3 wk intervals thereafter. Half of the eggs from each sample were examined live, and the remaining eggs were stained for 5–15 min in Bouin's solution prior to examination. Eggs were placed on a glass slide in 1 ml of filtered seawater and examined under a compound microscope at $\times 50$ -magnification using reflected light (darkfield background) from a fiber-optic source. Digital photographs of live embryos were taken with a 2-megapixel digital camera (Diagnostic Instruments Spot Insight camera) and analyzed using Image-Pro Plus, version 4.5. From days 3–12, individual photographs were taken of 3–5 embryos, but after day 12, 10–12 embryos were photographed on each sampling date. Embryos were only photographed if they were rotated at 90° to the sagittal plane. The image analysis system was calibrated using digital photographs of a stage micrometer set to the height of the midplane of crab embryos: the mean value (pixels \cdot mm⁻¹) from three digitized images was used. Measurements were made by first outlining the embryo on the computer screen using the computer mouse; if the inner and outer embryo membrane were clearly separated (as was often the case during the first 90 d of development), then the inner membrane was outlined. If the embryo outline was clearly defined and free of background clutter, then the automatic tracing option was used. The outline was then captured using a smoothing value of 5 (on a scale of 1–9). For the first 3 mo, digital measurements collected for each embryo included area (A), maximum diameter (L), minimum diameter (W) and mean diameter (calculated from 180 measurements taken at 2° intervals around the perimeter). After the embryo became apparent at day 114, the area of the yolk mass was determined, and the percentage of apparent cross-sectional area occupied by yolk (PAY) was calculated. After day 192, 10 additional embryos were photographed where the eyespot was rotated to the top central position, and L and W of the pigmented eyespots were measured. In addition to the measured parameters, three metrics of embryo shape were calculated, including ellipticity (L/W), elongation ($[L - W]/[L + W]$), and circularity ($\pi LW/4A$) (Hidalgo et al. 2005). Measurements were output directly to an Excel spreadsheet for analysis.

When hatching began, the female crab was placed into a 70-L plastic tub fitted with a bulkhead fitting and drain on the lowest portion of the sidewall. Tubs received flowing sand-filtered seawater at a rate of 4–5 L \cdot min⁻¹ at ambient temperature ($4.8 \pm 0.4^\circ\text{C}$) during the hatching period. Larvae exiting the drain passed up through an exterior standpipe and into a fine mesh net. The net was removed daily and larval volume measured to the nearest 0.5 mL in a graduated cylinder. Mean hatching date was determined as the weighted average of larval production over time, that is, by multiplying the daily volume of hatched larvae by day-of-the-year, summing the products over time and dividing by total volume of larvae released.

Stage Descriptions

Stages of embryonic development were defined using two different methods. One was the traditional method using developmental changes that are visually observable in the stained or unstained embryos. However, no standard criteria exist by which to define stage endpoints, so stage definitions tend to be subjective.

As a general guide, reference was made to descriptions of embryonic development in snow crabs *Chionoecetes opilio* (Moriyasu & Lanteigne 1998) and red king crab (Nakanishi 1987).

In the attempt to develop a more objective morphometrically-based method of classifying embryonic stages, cluster analysis of embryo morphometry was used as a second technique (Ludwig & Reynolds 1988) using SAS PROC CLUSTER. By grouping together samples (dates) with similar characteristics, the clustering technique should identify groups of dates (which may represent periods of development if they are sequential) during which the embryo metrics are most similar to each other and thus represent stages of development with little change. Different stages of development should be grouped into different clusters. Sampling units were defined as dates (with individual embryos as replicates), and the method used was average Euclidean distance. However, the actual sample dates were not used as input data because they would have influenced the resulting order of clusters, whereas the goal of this analysis is to determine the stage of development in randomly sampled (wild) crabs whose fertilization dates are unknown. All 11 measured and calculated metric parameters were used in the initial cluster analysis except yolk area (which was only used for calculating percent area of yolk, PAY). Subsequent analyses were made by removing calculated indices until the clusters were aligned in best chronological order. The number of clusters defined is somewhat arbitrary, with a maximum up to the total number of samples. However, selection of an appropriate number can be guided by looking for peaks in the pseudo-*F* statistic, and valleys in the pseudo-*r*² statistic (SAS 2004). Values of morphometric parameters are given in the text as Mean \pm 1 SD.

The utility of this method for classifying the stages of eggs from wild crabs with unknown developmental histories depends on the conditions under which it is applied. As a test, sampled data from three different crabs with embryos of different known ages were included and classified along with data from crab #1. Each test sample consisted of measurements from 10 embryos, and each crab had been held at different temperatures, as follows: Crab #2, 2°C, 167 d; Crab #3, 4°C, 192 d; Crab #4, 6°C, 223 d.

RESULTS

Embryo Development

Female crab #1 molted on January 17, 2004, was grasped and mated by the male the next day (18 January) and was observed to have extruded eggs on the next day, 19 January 2004, which was designated as day 0. Water temperature increased gradually from 4°C to 6°C during the study; mean temperature was $5.2^\circ\text{C} \pm 1.2^\circ\text{C}$ during the incubation period (January 19, 2004 to March 3, 2005) (Fig. 1). The following description of development is organized according to the 12 stages defined by morphometric cluster analysis (see later).

Stage 1 (Cleavage)

During this period dividing cells were easily distinguishable prior to blastodisc formation, and little change in morphometry occurs. Eggs were initially lavender colored; first divisions occurred on day 4, but true 2-cell stages were not observed. By day 7, all embryos were multicellular, including 4-cell stage and 8-cell stages, and a few with 16 cells (Fig. 2A, a). On day 9, most embryos were at the 32-cell stage and one was 64-cells. Nuclei were apparent as diffuse light-colored spots in the center of each

Figure 1. Water temperature during embryonic development of blue king crab (*Paralithodes platypus*). Mean temperature (heavy line) was 5.2 ± 1.2 C.

cell. Embryos were separated from the outer egg membrane, which had increased slightly in size. Cell numbers continued to double at 2-d intervals, to 64 on day 10, 128 on day 12, 256 on day 14, etc. By day 19, yolk had broken up into small irregular globules and cell borders were no longer distinct, although nuclei were apparent on eggs preserved in Bouin's. This period corresponds to visual stages V1-V2 in Table 1.

Stage 2 (Blastula-Gastrula)

Individual cells and structures are not visible. The blastodisc became apparent on day 28 and the blastopore was visible on some eggs (Fig. 2B, b). Embryos continued to decrease in size until day 72, but developmental changes were not discernible. Corresponds to V3-V5.

Stage 3 (V-embryo to Nauplius)

During this period embryonic lobes are becoming visible and are increasing in size. On day 114, the V-shaped embryo became distinct from the yolk in stained eggs; it is now clear in profile and can be measured (Fig. 2C, c). By day 121, most embryos had distinct lobes that would become the antennules, antennae and mandibles. Optic lobes are diffuse and indistinct, and the abdomen is a diffuse round lobe at the base of the "V". By day 128, most embryos have distinct mandibles, and by day 143, the optic lobes are clearly defined. By the end of this stage, the antennules and antennae are elongated, and the abdomen is distinct. This stage corresponds to V-6, and is similar to stage 31 (metanauplius) of Nakanishi (1987) (abbreviated as N-31), or to stage 6 (pre-nauplius) of Moriyasu and Lanteigne (1998) (abbreviated as ML-6).

Stage 4 (Prenauplius)

Defined by a single observation on day 157 (Fig. 2D, d). The optic lobes are large and rounded. Rudiments of the antennules and biramous antennae are clearly defined, the latter with a medial epipodite. The mandible is forming medial to the antennae. The abdomen is folded over the embryo for about half of its length. Size and shape of the embryo is identical to that of Stage 1, equivalent to stage V-7 and similar to N-33 or ML-8.

Stage 5 (Metanauplius)

Observed on day 171 only. Optic lobes extend lateral to the rest of the embryo. The tail is about two-thirds the length of the embryo. The telson is forked, but setae are not apparent. Maxilliped rudiments are barely visible lateral to the tail. Embryo area and diameter surpass the starting values. Included in V-7, similar to N-38 or ML-9.

Stage 6 (Eye Formation)

The eyes are large, lightly pigmented, and extend almost to the edges of the egg (Fig. 2E, e). The telson has 6 or 7 spines (or setae) and reaches the anterior margin of the optic lobes. Lateral appendages have setae. Up to four chromatophores can be seen. Similar to N-42 (day 201) or ML-10.

Stage 7 (Chromatophore Formation)

This is a period of rapid eye growth and formation. The eyes changed from strongly pigmented crescents (Fig. 2F, f), to being oval-shaped (Fig. 2G, g). Six to eight chromatophores are visible on each side. Maxillipeds are elongated with rudimentary setae. In side view, the embryo takes up one-third of the egg. The telson extends past the optic lobes. Similar to N-44, this stage and the next are included in stage V-8.

Stage 8 (Diapause)

Yolk is divided down dorsal midline into left and right halves, as well as distinct anterior (pinkish) and posterior (orange) lobes (Fig. 2H, h). The embryo is crescent-shaped and wraps three quarters of the way around the yolk, covering the entire surface in ventral view. Embryo area and diameter reach a "plateau," and do not increase further until after day 329. Growth rate of eye length slows down, and eye width levels off. Heartbeat becomes distinct.

Stage 9 (Eye Enlargement)

Embryo takes up >50% of egg in side view (Fig. 2I, i). Posterior lobe of yolk is visibly reduced, relative to anterior lobe. Yolk lobes are clearly separated in dorsal view (Fig. 2J, j). This stage is equivalent to V-9.

Stage 10 (Rapid Growth Phase)

Area, length and width of embryo increase rapidly. Dorsal edge of yolk is separated from the perimeter of the embryo case. All measured dimensions start to increase. Equal to V-10.

Stage 11 (Yolk Depletion)

Area of yolk decreases rapidly, as other dimensions increase during this period of rapid growth. Maxillipeds are well defined and pigmented (Fig. 2K, k). Equal to V-11.

Stage 12 (Hatching)

Hatching starts. Embryo length and width, and eye length and width reach maximum values. Ommatidia develop a greenish-yellow fringe, producing a "halo" effect around eye. PAY reaches lowest value. Anterior and posterior regions of yolk become distinct, and the latter is reduced to individual lipid globules. The presence of hemocyanin gives the embryo a bluish tinge. Day 395 (Fig. 2L, l) is midpoint of hatching period. Equal to V-12.

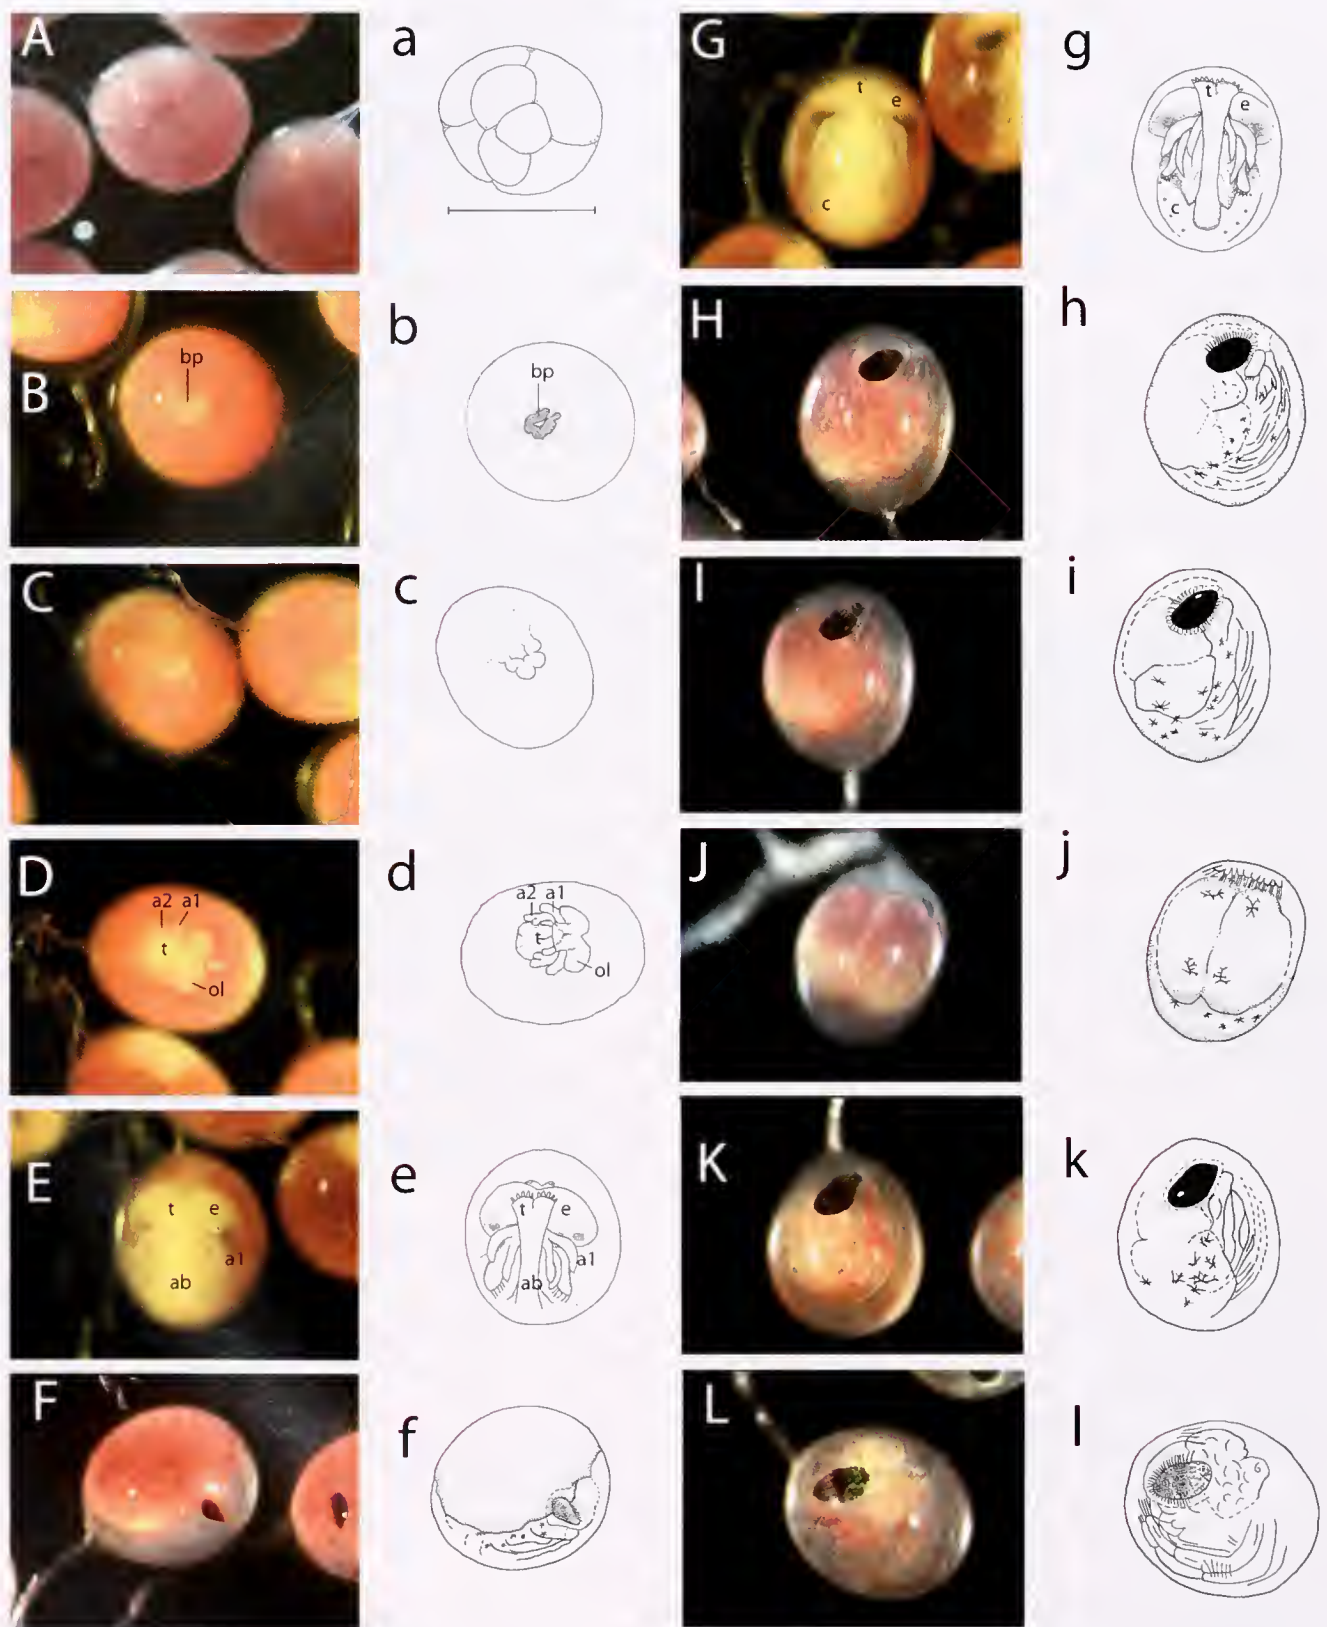

Figure 2. Blue king crab embryo development based on morphometric staging: A, (a) Stage 1, day 7, 16 cells (scale bar = 1.0 mm); B, (b) Stage 2, day 28, blastodisc, stained; C, (c) Stage 3, day 114, "V"-embryo, stained; D, (d) Stage 4, day 157, stained; E, (e) Stage 6, day 192, stained (note setae on maxillipeds and telson); F, (f) Stage 7, day 206; G, (g) Stage 7, day 206, stained; H, (h) Stage 8, day 268; I, (i) Stage 9, day 305; J, (j) Stage 9, day 305, dorsal view showing divided yolk; K, (k) Stage 11, day 367; L, (l) Stage 12, day 395, hatching. Abbreviations: a1, antennule; a2, antennae; ab, abdomen; bp, blastopore; c, carapace; e, eye; ol, optic lobe; t, telson.

Figure 3. Mean ± 1 SD of area for blue king crab (*Paralithodes platypus*) embryos, from fertilization to hatching.

Morphometric Changes

When first extruded, the mean area of eggs was 0.95 ± 0.02 mm² (Fig. 3), and length and width were 1.17 ± 0.05 mm and 1.03 ± 0.03 mm, respectively (Fig. 4). Mean area gradually declined to a minimum of 0.83 ± 0.03 mm² on day 72 then began increasing steadily. Length and width followed similar trends. Embryo area, length and width reached a plateau between days 240 and 329 and then increased rapidly from day 353 to day 381, when hatching started. Maximum values were reached for embryo length (1.37 ± 0.02 mm) on day 381, for embryo area (1.28 ± 0.05 mm²) on day 388, and for embryo width (1.19 ± 0.03 mm) on day 395. In profile view, yolk occupied 100% of the area of the egg until day 121, when the embryo first became apparent, and PAY was 97.8% (Fig. 5). Yolk area declined as the embryo grew, with a steep decline between days 157 and 206. By day 305, PAY was <50% of total profile area. From day 353 to day 381, during the last month before hatching started, PAY declined most rapidly, from 37% to 12.5%. PAY leveled off during hatching, but reached its lowest value of 12% on day 395. Eye pigment was first observed on day 192, when length and width of the pigmented area were 0.155 ± 0.017 mm and 0.077 ± 0.011 mm, respectively (Fig. 6). Eye length and width both increased steadily thereafter, with the rate of increase leveling off after day 305. Eye length and width increased rapidly after day

Figure 4. Mean ± 1 SD of minimum (width) and maximum (length) diameters for blue king crab (*Paralithodes platypus*) embryos.

Figure 5. Mean ± 1 SD of percent yolk visible in side view of blue king crab (*Paralithodes platypus*) embryos.

353, reaching maximal values on days 395 (0.431 ± 0.012 mm) and 388 (0.265 ± 0.016 mm) for length and width, respectively.

Stage Classification

A total of 39 samples (dates of observation) were used for the analysis. Table 1 defines the stages, starting and endpoint dates (as day number), duration of each stage in days, and percent of total development, as defined by both the traditional (visual) method and the morphometric (clustering) method. The best results were obtained after eliminating the circularity and ellipticity metrics, which showed no linear trend over time. Similar results were obtained regardless of whether calculations were made using PAY as raw data, or after angular or log transformation. Clusters were selected in more-or-less chronological order, even though day number was not used as a variable. Twelve stages were defined by both methods, those stages found to be similar by both methods appear on the same line. In the cluster analysis, a sharp change occurred in both statistical guidelines (the pseudo-*F* and pseudo-*r*² values) after 11 clusters. In the dendrogram (Fig. 7), a horizontal line drawn at an average Euclidean distance of about 0.15 (on the vertical axis) would cut across 11 vertical branches, each of which defines a cluster. Two clusters (days 9 and 157) were misplaced, so the former was combined with Cluster 1 and the latter removed

Figure 6. Mean ± 1 SD of length and width for the pigmented eye of blue king crab (*Paralithodes platypus*) embryos.

TABLE 1.

Developmental stages of blue king crab. Stages were defined either by the traditional visual method, or by analysis of morphometries. Begin and End are midpoint days between observations and are numbered from fertilization; Days is duration of stage; Percent is duration relative to complete development. Similar stages occur on same lines. Some stages were represented by a single sampling date.

Stages Assigned by Morphometrics		Values at Beginning of Stage								Stages Assigned by Visual Method				
		Begin	End	Days	Percent	Egg Area	Egg Length	Eye Length	Pct Yolk	Stage	Begin	End	Days	Percent

from it. One additional cluster was further split posthoc into Clusters 2 and 3, leaving 12 useful clusters as stages.

Embryos from three test crabs were classified into three different stages relative to those of Crab #1. Embryos from Crab #2, incubated at 2°C (167 d old) were developmentally delayed because of colder temperatures and were classified as stage 3 (between days 128 and 135 for Crab #1). Embryos from Crab #3, raised at 4°C (192 d old), were classified as a distinct cluster between stage 5 (171 d) and stage 6 (192 d). Embryos from Crab #4 (6°C, 223 d) were more advanced because of warmer temperatures and were classified as a distinct cluster between stages 8 (282 d) and 9 (305 d).

Hatching

Hatching of larvae was first observed on February 2, 2005, but the female crab was not placed into the isolation tub until February 4, because of space limitations, and larvae were first collected the next day. Therefore, it is likely that several days of larval hatching were missed. On the first night of larval capture 35 mL of larvae were collected (Fig. 8), a much larger volume than on subsequent days. Whereas unusual, such spikes occasionally occur when hatching is delayed because of disturbance or disruption of light cycles. Measurable numbers of larvae were collected for 31 d, and the mean date of hatching was February 12 (day 390). If the 2 d prior to the beginning of larval collections (after female isolation) are included, hatching lasted for a total of at least 33 d.

DISCUSSION

During early stages, BKC embryos developed at almost the same rate as described for red king crab by Nakanishi (1987), who reported that cleavage was first seen on day 4, a distinct 2-cell stage was not observed, the 4-cell stage appeared on day 5, 8-cells on day 8, and cell numbers doubled daily thereafter. Development of BKC embryos slowed between days 240 and 330 (mid September to mid December) and then increased rapidly until hatching.

The total length of development was longer (390 d to the mean hatch date) than that for 12 primiparous red king crabs (365 d) or for 19 multiparous red king crab (326 d) that were held at an average temperature of 6°C (Stevens & Swiney, in press). Length of hatching, although possibly underestimated at 33 d, was slightly longer than the mean of 28 days determined for 23 BKC in 2004 (Stevens, in press), yet similar to that for red king crabs, which averaged 31 d regardless of parity (Stevens & Swiney, in press). Snow crabs in the Gulf of St. Lawrence also have a 2-y spawning cycle like BKC, but embryos require 2 y to develop (Moriyasu & Lanteigne 1998), versus 13 mo for BKC. Moriyasu and Lanteigne (1998) described 14 developmental stages that roughly correspond to the 12 identified for BKC, plus two earlier stages prior to, and during, funiculus formation; analysis of morphometry did not distinguish such stages in BKC embryos. Nakanishi (1987) examined red king crab eggs at more-or-less weekly intervals, and subsequently described 53 stages.

Crustacean growth and development rates increase with temperature, as has been shown for larval stages of both red (Nakanishi 1981) and southern king crab (Anger et al. 2004), and snow crab (Kogane et al. 2005) and embryos of northern shrimp *Pandalus borealis* (Brillon et al. 2005). Crustaceans from warmer water environments typically have shorter embryonic development on the order of days to weeks. With short developmental periods, observations made at daily intervals are often different enough to be characterized as individual stages. For example, embryos of the fiddler crab *Uca lactea* require an average of 15.4 d to develop, reach the 32-cell stage within 24 h and can be categorized into 15 distinct stages (Yamaguchi 2001). Embryonic development of the redclaw crayfish, *Cherax quadricarinatus*, requires 42 d at 26.0°C, and was categorized into 10 prehatching and 3 posthatching stages (Garcia-Guerrero et al. 2003). Unlike crabs in the families Lithodidae and Paguridae, *Aegla platensis*, a riverine anomuran in Brazil, develops through the zoea and decapodid stages (equivalent to the megalops or glaucothoe) inside the egg and hatches after 35 d (Lizardo-Dandt and Bond-Buckup 2003).

Because of the great disparity in development time, there is no

Figure 7. Dendrogram of blue king crab (*Paralithodes platypus*) embryo stages as defined by cluster analysis. 12 clusters are identified, one of which (#4, day 157) was misclassified.

standardized scheme for characterizing developmental stages of crabs or any other decapod crustacean. The number of described stages ranges from 10–15, depending on the length of development and the utility of each stage in describing changes observable by eye. The use of embryo morphometrics is a more quantitative method, and may be a useful approach for comparing development between different populations, environmental conditions or species. Lavarias et al. (2002) used embryo morphometry to describe development in the freshwater prawn *Macrobrachium borellii* and found that predetermined stages could be identified using four metrics, but they did not use a multivariate approach to classify stages based on their similarity. In order for this approach to be useful, however, it requires a larger number of samples than the number of expected stages. Therefore, for species with short development periods, multiple samples per day would be required. However, stages defined by multivariate analysis, whereas relatively easy to construct using morphometric measurements, are not a substitute for examining the embryo by eye to determine the relative development of various appendages, chromatophores and other organs, and some samples (e.g., day 157) could not be accurately classified without visual observations. Examination of embryos from the three extra crabs, whereas not definitive because

Figure 8. Total volume of larvae hatched each day by the single blue king crab (*Paralithodes platypus*) used in this study.

of the different holding temperatures, does indicate that unknown embryo samples can be classified on a relative scale of development. A more definitive system could be developed by employing classification and regression tree (CART) analysis to define discrete developmental stages based on specific criteria.

The techniques of morphometric analysis used in this study are partly adapted from those used in the medical and veterinary sciences for classifying the “quality” of sperm cells (Verstegen et al. 2002). Automated techniques such as computer-assisted sperm analysis (CASA) (Verstegen et al. 2002) and automated sperm morphometry analysis (ASMA) (Hidalgo et al. 2005) could provide new insight into the study of crustacean embryo development, revealing differences too subtle to be detected by the naked eye that may result from environmental change, anthropogenic disturbance or pollution. Morphometric classification of gametes and embryos may also be useful for identifying and selecting high-quality brood stock for the aquaculture industry or for preservation of endangered species.

ACKNOWLEDGMENTS

The author thanks R. MacIntosh and L. Rugolo for capturing and shipping the crabs to Kodiak, and S. Persselin and S. VanSant for assistance with various aspects of the experiment. Student interns B. Neslund, M. Moore and R. Ellingson assisted with feeding and maintaining the crabs. Thanks to G. Jensen, L. Rugolo and several unidentified reviewers for their constructive comments.

TIMING AND SEASONALITY OF THE TERMINAL MOLT AND MATING MIGRATION IN THE SPIDER CRAB, *MAJA BRACHYDACTYLA*: EVIDENCE OF ALTERNATIVE MATING STRATEGIES

ANTONIO CORGOS, PATRICIA VERÍSIMO AND JUAN FREIRE*

Departamento de Biología Animal, Biología Vegetal e Ecología, Universidade da Coruña, Campus da Zapateira s/n E-15071 A Coruña, Spain

ABSTRACT Timing and synchronization at individual and population levels of the processes related to the terminal molt, gonad maturation, accumulation of energy reserves and migration in the spider crab *Maja brachydactyla* are analyzed. Also, the intra and intersexual variability is established. Two hypotheses are tested to explain the temporal and population variability: (1) physiological hypothesis: males and females begin migration when they reach the appropriate physiological stage (the optimum level of energy reserves) and (2) mating opportunities hypothesis: the timing of the migration maximize mating opportunities and mate quality. Our results show that males carry out the terminal molt before females, the former having a peak in July and the latter in August. The onset of gonad maturity in females occurs between two and three months after they have reached morphometric maturity (starting in October), coinciding with the period prior to and during the mating migration to deep waters. In an analysis of the spermathecae of primiparous females, it was found that practically no mating activity occurred in shallow waters, whereas the first copulations took place in the migration corridor. However, probably most of the mating activity occurs in deep mating grounds. Males reached gonad maturity prior to morphometric maturity. No differences were observed in the physiological status (muscle, gonad and hepatopancreas relative mass) between migrating and nonmigrating crabs, which is a clear indication that the physiological hypothesis does not hold true for this species. A higher percentage of postmolt crabs were caught in the migration corridor than in shallow waters. The physiological condition improved over time in males and females in the specimens caught in the shallow area as well as in the migration corridor. Therefore, the crabs that start migrating first did so in poorer physiological condition. Moreover, the early migrators had a significantly lower mean size than the late migrators. Our results suggest that variability within populations and between sexes are related to the different reproductive strategies and not to a physiological limitation. Thus, the poor-quality males (with a reduced competitive ability) would migrate at the beginning of the season to maximize the mating opportunities that would not be feasible if they had to compete with the late migrators, which are larger in size and in better physiological condition. Sperm competition is not clear in *M. brachydactyla*, but all evidences point at last male preference for fertilization of eggs.

INTRODUCTION

Juveniles of *Maja brachydactyla* (Bals 1922, see Neumann 1998 for taxonomic status, corresponding to the North Atlantic species previously known as *M. squinado*) live primarily in shallow waters (González-Gurriarán & Freire 1994, Hines et al. 1995, Le Foll 1993, Meyer 1993, Sampedro 2001, Freire et al. 2002). During the summer of their second or third year of life (depending on the recruitment season) these crabs carry out the terminal molt, associated with the onset of sexual maturity [Corgos 2004, Corgos & Freire (in press), Corgos et al. (Submitted), Freire et al. 2002, González-Gurriarán et al. 1995, Le Foll 1993, Meyer 1993, Sampedro et al. 1999]. Between late summer and early autumn adult specimens carry out a reproductive migration to deep waters as has been observed in different areas on the European coast (Camus 1983, Edwards 1980, Freire & González-Gurriarán 1998, Freire et al. 1999, González-Gurriarán & Freire 1994, Kergarion 1976, Kergarion 1984, Latrouite & Le Foll 1989, Le Foll 1993, Meyer 1993, Stevcic 1973). Although information is scarce on the mating behavior of the spider crab in the field, based on available evidence mating is known to take place mainly in deep waters, where aggregations could be formed (González-Gurriarán et al. 2002). The terminal molt, gonad maturity, migration and mating are factors that are closely interrelated and play an important role in the life history of the spider crab, because they will determine drastic changes in the spatial structure and demography of the populations and are fundamental in terms of reproductive success.

It has been widely documented that migrating animals store energy reserves before they begin to migrate to ensure the success of the migration (Dingle 1996). In the spider crab, migration entails a drastic change in activity (rapid movements of over 1–10 km · day⁻¹, after a juvenile phase with only small-scale movements (10s or 100s m · day⁻¹, Bernárdez et al. 2005, Freire & González-Gurriarán, 1998; González-Gurriarán & Freire, 1994; González-Gurriarán et al. 2002; Hines et al. 1995). This migration, however, takes place after the terminal molt—a physiologically and energetically critical process. Therefore, during a short period directly after the molt and prior to migration, the processes related to the recovery after ecdysis and the storage of the energy needed for migration must be carried out. Differences between males and females in the timing of migrations in other geographic areas have been reported; particularly the fact that males start to migrate before females (Stevic 1973). This differential behavior may be related to the reproductive strategies of the two sexes, as has been observed in other vertebrate species and other arthropods (Morbey & Ydenberg 2001).

Spider crab males compete for females, which gives rise to agonistic interactions (information based on direct observations by fishermen of occasional matings in shallow waters), and females may mate with several males (González-Gurriarán et al. 1998). Information based on observations of the mating activity of crabs held in captivity and at sea would indicate that males and females mate in hard carapace condition (no mating has ever been observed immediately after the molt). It is possible for ovigerous females to mate, and courtship prior to copulation does not take place, nor does pre or postcopulatory mate guarding (González-Gurriarán et

*Corresponding author. E-mail: jfreire@udc.es

al. 1998). This mating behavior differs from the characteristics defined for other majids (Claxton et al. 1994, Jones & Hartnoll 1997, Sainte-Marie et al. 1999). The fact that females have a hard carapace during mating determines the characteristics of the mating system. On the one hand, it means that the existence of mate guarding aimed at protecting females with a soft carapace from predators is not necessary for these crabs (e.g., Hartnoll 1969, Jivoff 1997a, Wilber 1989) and/or ensuring the paternity of the brood (Diesel 1991, Jivoff 1997a), although postcopulatory mate guarding has been observed in hard-shell females of *Chionoecetes opilio* (Claxton et al. 1994). On the other hand, in the case of the spider crab, all the adult females are receptive, which means that the operative sex-ratio, defined as the number of sexually active males versus the number of fertilizable females (Emlen & Oring 1977), is equal to the effective sex-ratio.

In other majids, sperm competition tactics that favors last male's paternity has been observed (Diesel 1990, Rondeau & Sainte-Marie 2001, Sainte-Marie et al. 2000), but this is not clear in *M. brachydactyla* (González-Gurriarán et al. 1998; Freire, unpublished data).

The timing and synchronization of the biological processes associated with reproductive migrations, at the individual and population levels, and the sexual differences observed in the spider crab may be explained by 2 sets of alternative hypotheses:

Physiological hypothesis: males and females start migrating when they have reached the appropriate physiological status (an optimum level of energy reserves). Therefore the variability within populations and sexes would be related to the physiological stage, depending on the timing of the terminal molt and the energy recovery rate. Both processes may be variable between sexes, with the energy needed for reproduction, and among body sizes.

The physiological hypothesis could be tested using the following predictions: (1) The physiological condition of the postpubertal adults caught in the migration corridor would be better than that of crabs still remaining in shallow waters. This pattern should be observed throughout the entire migration period. The physiological condition during the migration season would improve gradually in crabs from shallow waters, whereas it would remain relatively constant in time in individuals captured in the migration corridor (Fig. 1). (2) Sexual differences in timing would depend on the differential physiological condition of each sex, related to differences in the timing of the terminal molt.

Mating opportunity hypothesis: the timing of the migration should maximize mating opportunities and mate quality. Once a minimum physiological condition is reached, males would migrate at the appropriate time to intercept and mate with the greatest possible number of females in the mating habitats (in the spider crab these would include zones where females may be intercepted during migration and/or in deep waters). The variability within populations and sexes would be related to different reproductive strategies and not to a physiological restriction (possibly once a minimum level of energy reserves has been reached). According to this hypothesis, the intrasexual variability would be determined by the interindividual differences in quality.

The mating opportunity hypothesis could be tested using the following predictions: (1) At any given moment, crabs in migration and in shallow waters would not necessarily exhibit any differences in their physiological condition. (2) Poorer quality males (in the case of crustaceans, animals having a smaller body size and/or lower robust physiological condition) would carry out mi-

Figure 1. Physiological hypothesis. Temporal evolution of the physiological condition in a cohort of adults after the terminal molt (see Introduction for details).

gration earlier to maximize the possibility of mating encounters before high-quality males arrive to the mating grounds. Therefore, the physiological condition would improve throughout the migration period in both shallow waters and the migration corridor.

From the standpoint of males, mating probability depends on the abundance of females and on the competition among males, which means that the temporal distribution of mating opportunities throughout the season is probably unimodal. At the beginning, mating probability would be low owing to the absence of females in the mating zones. As females start arriving, these odds would likely increase until they reach a maximum value, then the probability would diminish, because the density of males would attain a maximum and the competition among them would cause mating probability to decrease (Fig. 2).

According to the mating opportunity hypothesis, early migrating males would be smaller and have a poorer physiological condition, but they would be the first to arrive at the mating zones. Besides being able to mate with females during migration, they would have a higher probability of mating with the first females to arrive at the mating zones (Fig. 2, A). The density of females would increase over time, but so would the density of males, so the percentage of intercepted females would gradually decline because of the competition (Fig. 2, B), until it reaches a minimum level that would coincide with the maximum density of males (Fig. 2, C).

Late migrating males would arrive at the mating zones later, but they would be larger in size and in stronger physiological condition (high quality males), which means that they would be better competitors than the early migrators. As density of females increases, the mating probabilities of these males would increase (Fig. 2, B) until a maximum value is reached, coinciding with the maximum density of females in the zone (Fig. 2, C).

For females the optimum strategy would be to mate with the males of the best quality available at any given moment. Males with larger ornaments or weapons, greater body size, or higher rates of courtship showed greater survivorship or longevity (Jennions et al. 2001). From this standpoint late migrants should be genetically superior, conveying genetic benefits to females by rising the mean offspring fitness caused by inheritance of "good genes," that may enhance survivorship or longevity of

Figure 2. Mating opportunity hypothesis. A, B and C represent 3 periods corresponding to the initial, intermediate and final stages of migration (see Introduction for details).

offspring and increase the sexual attractiveness (Jennions & Petrie 2000).

This study is a detailed analysis of the timing and synchronization at the individual and population levels of processes related to the terminal molt, gonad maturation, accumulation of energy reserves and migration in the spider crab. Intra and intersexual and intrapopulation variability in the earlier mentioned processes are analyzed. Our results will allow comparison, at least in part, the hypotheses proposed earlier related to the causes of the timing and synchronization of the processes linked to migrations.

MATERIAL AND METHODS

Monthly samplings were carried out between December 1997 and November 1999. From late summer until autumn, sampling effort was increased to obtain more detailed information on the migration of adults. Sampling was carried out using experimental traps (50-cm height, with upper and lower diameters of 110 cm and 100 cm respectively, and an entry of 22 cm and a 50-mm mesh, Corgos and Freire, submitted a). Soak time was 24 h and traps were baited with fresh horse mackerel (*Scomber scombrus*). The sampling area was the Ría de A Coruña, a small oceanic bay located off the NW coast of Galicia (NW Spain). One shallow water (5–15 m) sampling station was selected in the inner area of the ría (Bastigueiro) and another one in deeper waters (25–30 m) in the central channel of the ría, which constitutes the migration corridor for postpubertal adults. In the inner area of the ría, where there is high abundance of *Maja brachydactyla*, sampling was carried out along a transect on the longitudinal axis of the ría where seven tows were carried out deploying the traps parallel to the coast. Tows were separated approximately 180 m from each other (Fig. 3).

The following data were recorded for each specimen captured: sex, morphometric maturity (Corgos 2004, Corgos & Freire, in

press, Sampedro et al. 1999), stage of the intermolt cycle (estimated by the hardness of the exoskeleton and the presence of a new internal carapace in crabs approaching molt, Sampedro 2001) and the relative age based on the degree of epibiosis and carapace wear (see Fernández et al. 1998), to distinguish the recent postpubertal adults from specimens that had reached maturity in previous years.

To analyze the reproductive stage and physiological condition of males and females, adult females and juvenile and adult males were sampled monthly from July to December 1998 (morphology of the abdomen allow to determine the maturity stage directly in females; Sampedro et al. 1999). The maturity stage of males was determined later based on their morphometry. Samples were obtained from shallow areas and the central channel, although for several reasons in the channel data were obtained only for females in September and November, and for males in November. Males with CL > 60 mm were selected and divided into size classes of 20 mm with a final class of specimens of over 160 mm. A sample made up of a maximum of 10 males belonging to each size class captured in the shallow area was transported to the laboratory. A sample of five males from the three larger size classes was obtained from the captures in the channel, because smaller-sized crabs were not caught in this area. Adult females with a CL > 100 mm were selected and grouped into size classes of 40 mm and a sample of 5 specimens from each size class of crabs caught in the shallow area and the channel was taken to the laboratory.

The crabs were dissected to determine the gonad maturity stage in females (following the classification proposed by González-Gurriarán et al. 1993, González-Gurriarán et al. 1998), gonad dry weight, fullness and the number of sperm masses in the spermathecae in the case of females (following the classification proposed by González-Gurriarán et al. 1993, González-Gurriarán et al. 1998), and the presence of spermatophores and gonad dry weight in males. The gonad, hepatopancreas and the muscle of the second right-hand pereopod of each specimen were extracted and held for

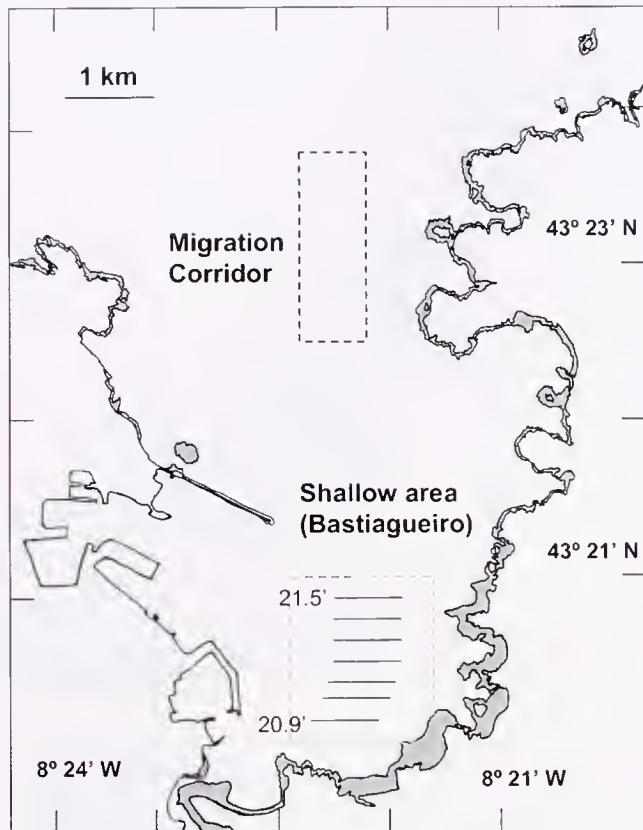

Figure 3. Location and sampling areas in the Ría de A Coruña. The transect comprising 7 trap tows in the inner shallow area is shown. Latitude is given for each tow on the transect (see Figure 6).

48 h at 60°C to obtain the dry weight (Corgos & Freire, in press). Morphometrically juvenile males were omitted from the analysis of the physiological condition.

Data Analysis

The energetic status of each individual was estimated by means of condition indices (CI) based on the dry weight of the gonad, muscle and hepatopancreas. The condition indices were estimated as the residuals of an allometric regression ($\log Y = \log a + b \cdot \log CL$) of the dry weight of each type of tissue respect to the carapace length (Fig. 4). The regressions were fitted to the data from the adult specimens caught between June and December 1998. Multiparous adults and juveniles were not included in the analyses.

The differences in the condition indices between migrators and nonmigrators over time, according to the predictions from the hypotheses, were analyzed using the time series corresponding to the condition indices of the crabs captured in shallow waters was fit to a second order polynomial regression: $CI = a + b \cdot \text{date} + c \cdot \text{date}^2$. Next, the condition index from specimens captured in the channel (these data were only obtained in some of the months) were compared with the trend of data from Bastiaqueiro. Significant differences between the two areas were accepted when the mean CI of the channel fell outside the 95% confidence band of the regression for the shallow area.

The molt stage was used as an additional body condition indicator, because the crabs in postmolt are in poorer condition than

those in the intermolt or premolt stage. The differences in the molt stage between migrators (early and late) and nonmigrators were determined by means of a log-linear analysis on the frequency of males and females in postmolt in Bastiaqueiro and in the channel in September and October 1998.

An analysis of variance (ANOVA) was performed to test differences on the mean body sizes of the migrators and nonmigrators, using data from males and females caught in Bastiaqueiro and the channel in September and October 1998.

RESULTS

Seasonality and Sexual Differences in the Terminal Molt

Adult males in postmolt began to appear in the catches from Bastiaqueiro in April, with their abundance undergoing a rapid increase, reaching high levels in June and a maximum in July. In September, the abundance of postmolt adults dropped sharply and continued to decrease more gradually until the complete disappearance of these crabs in December (Fig. 5). Postmolt females started to be caught in shallow waters in July, attaining maximum abundance in August. They dropped sharply in September and had practically disappeared by October (Fig. 5). The pattern was repeated in 1998 and 1999 and males were found to carry out the terminal molt one month earlier than females. The maximum numbers of postmolt adult males and females were found in July and August respectively. The terminal molt period in males lasted longer than in females (postmolt males were found from April until November in 1998). In 1999, there would seem to be greater synchronization, because adult males started to be caught in June.

Gonad Development and Mating

Adult females showed a clear seasonal pattern of gonad maturation. After the terminal molt, females had gonads in the early stages of development (between July and October 93% of the females were in stage I) and until November females did not attain more advanced developmental stages (II and III). No females were found with gonads in an advanced stage of development (IV) in either the shallow area or in the channel. In the channel 64% of the females had gonads in stage II and 27% in stage III between November and December. Therefore in females the gonads began to mature between two and three months after the terminal molt, during the period immediately proceeding or during their migration to deep waters.

The analysis of the spermathecae of primiparous females revealed that the number of matings in the shallow zone was low, because 97% of females ($n = 124$) showed empty spermathecae. An increase in mating frequency was observed in the channel, given that over 21% of the females studied ($n = 23$) had mated. These results would indicate that mating may be carried out in the migration corridors, but most likely it is in the deep waters where most of the mating activity takes place (Table 1). All the females analyzed exhibited a single sperm mass. In the shallow area, in contrast, two multiparous females that were captured had 7 sperm masses in each spermatheca, presenting differences in color and volume, which would point to the existence of long intervals between matings (González-Gurriarán et al. 1998).

After examining the gonads of the male crabs, it was evident that, unlike the females, gonad maturation takes place prior to morphometric maturity. Over 60% of the juveniles examined ($n =$

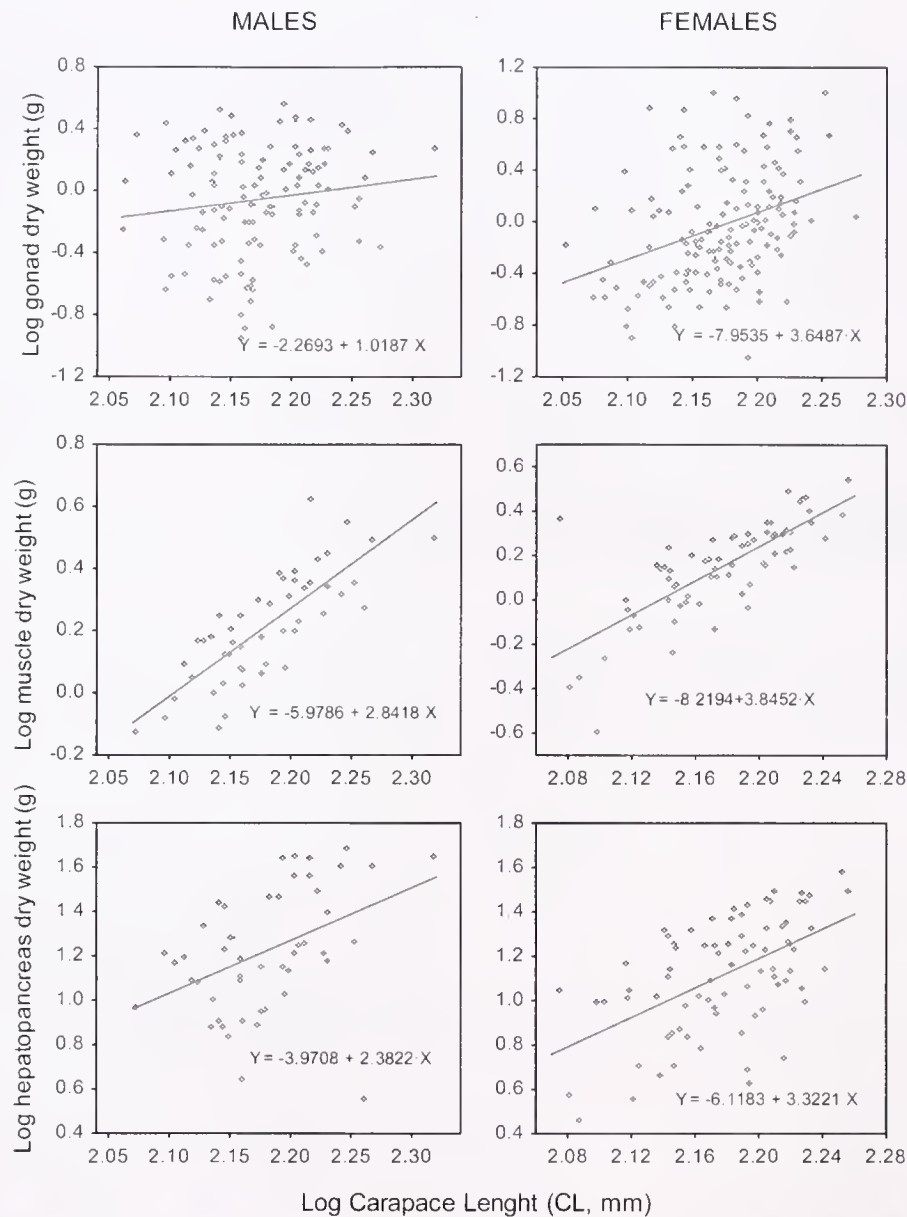

Figure 4. Relation between body size and dry weight of the tissue analyzed (gonad, muscle and hepatopancreas) to estimate the physiological condition of each sex. The allometric regression fitted in each case is shown.

382) had spermatophores, and more than 76% of the juveniles with a CL > 96 mm as well as all of the morphometrically mature crabs had spermatophores. Therefore, males are functionally mature and ready to mate immediately after the terminal molt (see Corgos & Freire, submitted a).

Sexual Differences in the Timing of the Start of Migration

Based on the sampling carried out in the inner ría, it was possible to carefully monitor the small-scale movements of the adults and the start of their migration (Fig. 6). In July 1998 the mean CPUE of males was much greater than that of females (4.2 and 0.5 crabs · trap⁻¹ respectively). Males were also found to be sparse around the innermost part of the ría and near the shoreline.

In August the average CPUE of females found in the inner ría increased (3.8 crabs · trap⁻¹), and males had moved to the outermost zone near the channel. By September, the large concentration of males in the outer part of the inner area had disappeared, which would imply that they had started migration, whereas the females had moved to the outer zone. In October, the few males left in the area started moving to the outer zone and leaving the area, whereas the females were concentrated in the outer part of the shallow area. In November, the catches yielded few adults, although some females were still found in the outermost area, which means that the females migrated between October and November. By December practically all the adults had left the area.

The catches taken in the channel confirm this seasonal migratory pattern (Fig. 7). They were concentrated in the months of

Figure 5. A comparison of the monthly evolution of the proportion of adult males and females in postmolt stage (related to total catches including adults and juveniles) captured in shallow waters.

September and October; however maximum catches of males were obtained in September and those of females in October. Males exhibited stable catches between September 25 and October 23 (Fig. 7). The first females, on the other hand, were caught on

September 25, from which time catches increased gradually until they reached a clear peak on October 23.

Body Condition at the Start of Migration

From July to December, adult males in Bastiagueiro underwent a progressive increase in the relative weight of the muscle, gonad and hepatopancreas (Fig. 8). It was only possible to compare the

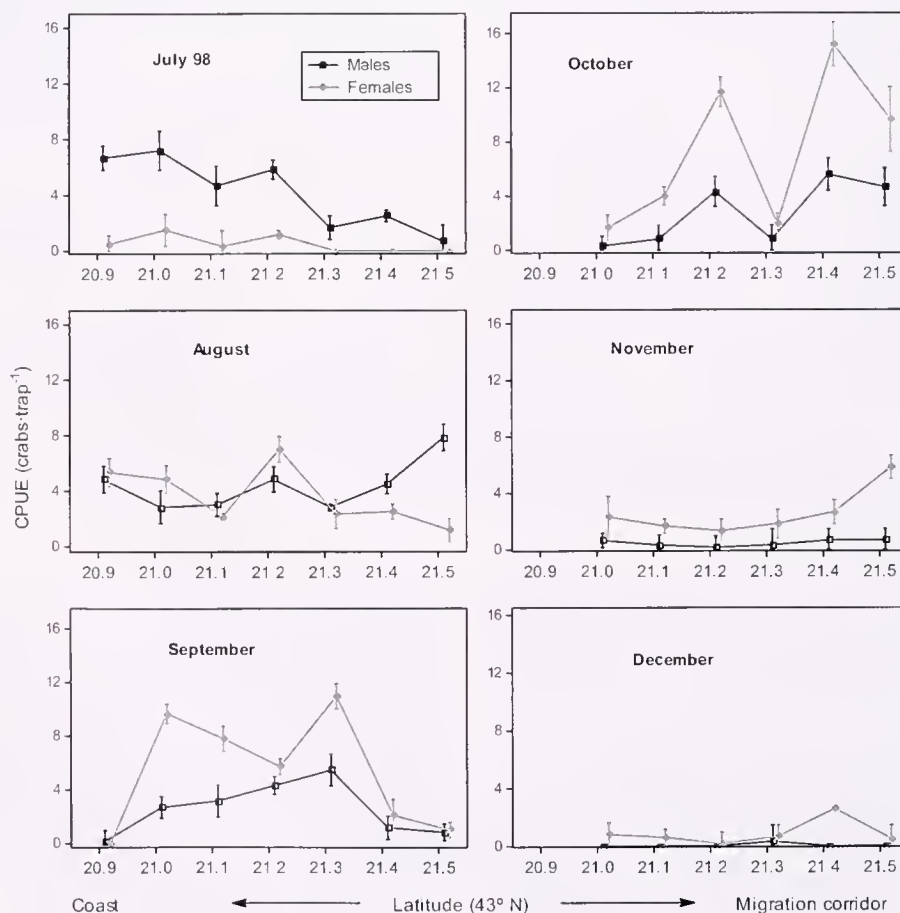

Figure 6. Spatial structure of the adult population in Bastiagueiro in the period prior to and at the start of migration. The catch per unit of effort is given (crabs · trap⁻¹ and a 95% confidence interval of the mean) along the transect sampled (each 10th of a degree is equivalent to 182 m) (see Figure 3).

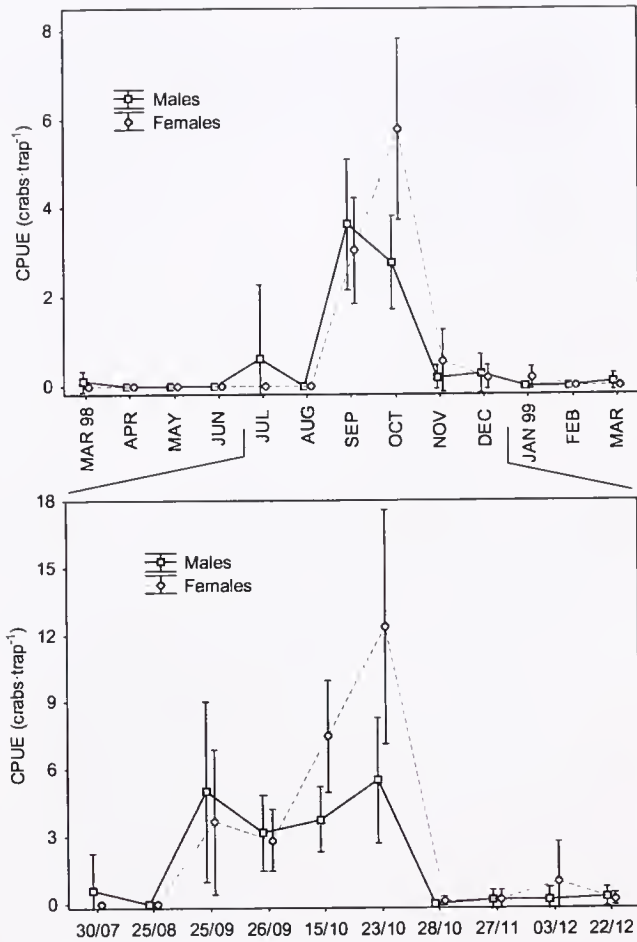

Figure 7. Abundance of adults in the channel (mean crabs · trap⁻¹ with a 95% confidence interval of the mean) during each month of the sampling (upper), and on each day of sampling during migration (lower) in 1998.

physiological condition in the channel zone (migrators) and shallow area (nonmigrators) in November. During this month migrators presented condition indices similar to those of nonmigrators in all the tissues analyzed.

The condition index in females found in the shallow areas showed a gradual increase in the case of the gonad, but this was not so in the case of the muscle or hepatopancreas (except for very low values in the latter tissue in September). The adult females captured in the channel had slightly higher gonad condition values in November as compared with the shallow zone, whereas no differences were observed in September (Fig. 9). The physiological condition of the muscle was similar in November, which was the only month in which information was available for the channel. The physiological condition of the hepatopancreas, however, was similar in the two areas in September and November.

The percentage of postmolt males and females in each zone was higher in September than October (Table 2), and in both months the percentage was higher in the channel than in Bastiagueiro (log-linear analysis of the effects of sampling station, date and sex on the percentage of specimens in the postmolt stage, showed the significant variables to be sampling station and date, $X^2 = 5.53$, $P = 0.35$). This would imply that the condition of the early migrators is poorer than crabs that migrate later.

Body Size at the Start of Migration

The mean size (CL) of males and females was compared between Bastiagueiro and the channel in September and October. Females were significantly larger than males, and in Bastiagueiro as well as in the channel for males and females, the largest sizes were found in October (ANOVA, $n = 1198$; effect of date and sex, $P < 0.001$; effects of sampling station and all interactions, $P > 0.2$). None of the interactions proved to be significant, which was an indication that the smaller-sized specimens of males and females started migrating earlier (Table 3).

DISCUSSION

This study provides evidence as to the existence of synchronization in the timing of the terminal molt, gonad development and migration in the spider crab. The inter- and intra-sexual differences related to these phenomena may reflect different types of behavior and reproductive strategies that would be compatible with the mating opportunity hypothesis discussed earlier. However, our results

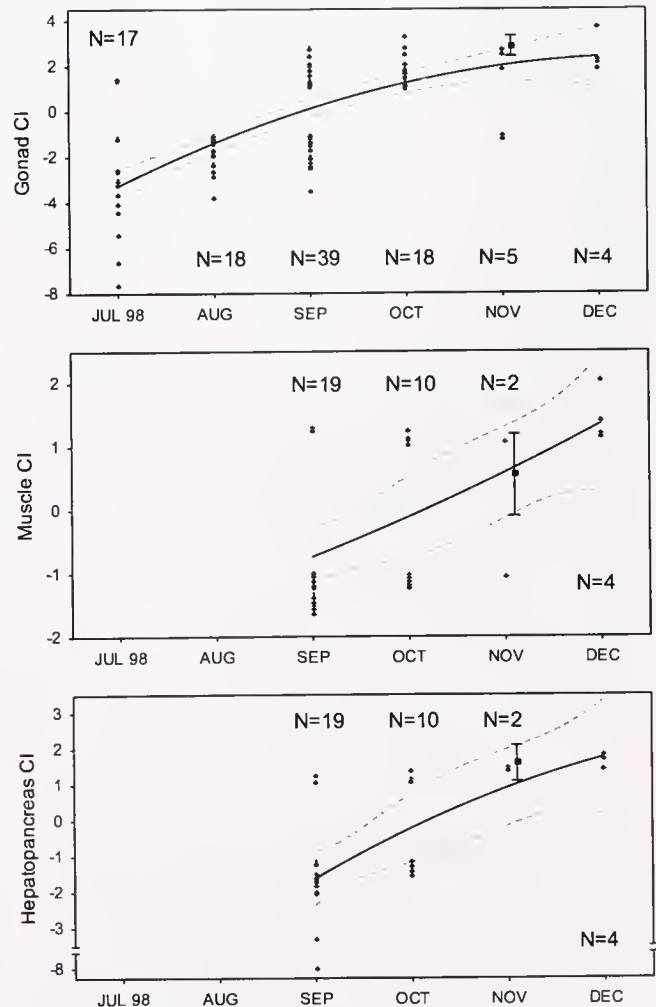

Figure 8. Temporal evolution of the condition index (CI) of each tissue in adult males in Bastiagueiro (individual observations, sample size for each month and polynomial regression with 95% confidence interval are shown) and in the central channel (mean and 95% confidence interval, only in November, $n = 14$).

Temporal evolution of the condition index (CI) of each tissue in adult females in Bastiagueiro (individual observations, sample size for each month and polynomial regression with 95% confidence interval are shown) and in the central channel (mean and 95% confidence interval, only in September and November, $n = 14$).

contradict some of the predictions made in the physiological hypothesis.

To mate, an organism must be in the appropriate physiological condition, as well as having a suitable location in space and time (Correa & Thiel 2003). In *M. brachydactyla*, males probably reach maturity and develop gonads before females to be physiologically prepared to mate at the time and place where the encounter with the adult female occurs. Considering the date when migration starts and the fact that in December and January, ovigerous females begin to appear in the catches in the shallow areas (unpublished data), aggregation and mating in deep waters must occur over the course of a short period. Because females have spermathecae, they are able to mate when their gonads are in early stages of development, fertilizing the broods later.

In the Ría de A Coruña, the terminal molt takes place in shallow waters between April and August. Males undergo the terminal molt one month earlier than females. González-Gurriarán et al. (1995) obtained similar results with this species under culture conditions, whereas in more northern latitudes, the cycle is delayed, owing possibly to the differences in the thermal regimen. In the

English Channel the crabs undergo the terminal molt in late summer and early fall and adults that have recently reached the post-pubertal stage start to be captured in August-September, presenting maximum catches in early fall (Le Foll 1993, Meyer 1993).

An analysis of the captures in the channel during the migration shows that over the entire period males and females migrated, as would be expected in a species where the females are polyandric (Zonneveld 1992). In view of the captures obtained in the migration corridor, males showed stable catches during the migration period without a specific peak, whereas females, which started migration at the same time as males, exhibited a clear peak on October 23, 1998, after which catches were virtually nonexistent. These results indicate that the migration of males is not as synchronized as that of females, rather males carried out migration gradually over a 30-day period, whereas most females migrated between October 15 and 28, 1998.

Mating takes place generally after migration, in the deep-water wintering habitats, although copulation could occur also during migration (21% of the females caught in the channel had sperm in the spermathecae). These data largely coincide with those reported by González-Gurriarán et al. (1998) in the Ría de Arousa, where the spermathecae of 100% of the primiparous females caught in the shallow zone were found to be empty. On the other hand, catches of multiparous females having several sperm masses, along with direct observations by fishermen, support the hypothesis that mating does occur in shallow waters, but probably re-

TABLE 3.

stricted to multiparous females. In latitudes located farther to the north, matings were observed in shallow waters from May to July on the Irish coast (Brosnan 1981), and starting in June on the French coast (Kergarion 1984). Based on these observations, these authors report that mating generally occurs in summer, although to support this hypothesis, it would be necessary to carry out an analysis of the spermathecae content of females in wintering habitats.

The analysis of catches in the shallow area and the migration corridor and condition indices may be used as indicators of the reproductive strategies of *M. brachydactyla*. The condition indices of the tissues analyzed were similar in the shallow area and the migration corridor (i.e., no differences were observed in the body condition between migrators and nonmigrators), which would clearly imply that the physiological hypothesis is not supported in this case. The physiological condition increased over time in males and females both in crabs caught in Bastiagueiro and the migration corridor. Consequently, crabs that migrate first, do so in poorer physiological condition. Moreover, the early migrators were smaller in size than the late migrators. These evidences support the mating opportunity hypothesis. Poorer quality males (smaller sized and in poorer physiological condition) migrated earlier, which gives them mating opportunities that would not be feasible if they had to compete with the late migrators that are larger in size and in better physiological condition.

In both majids (Conan & Comeau 1986, Elner & Beninger 1995, Ennis et al. 1990, Sainte-Marie et al. 1997, Rondeau & Sainte-Marie 2001, Stevens et al. 1993) as well as other decapods (Correa et al. 2003, Jivoff 1997b, Van Der Meer 1994, Wada et al. 1997) agonistic interactions have been observed between males prior to mating, in which the large-sized individuals exclude the smaller ones. At other times the small males are rejected by the females (Goshima et al. 2000). For this reason the larger-sized males are more likely to mate than the smaller-sized animals. This hypothesis is corroborated by observations in the field, where mating majid males were seen to be generally larger than the females (Brosnan 1981, Conan & Comeau 1986, Ennis et al. 1988, Paul 1992, Powell et al. 1972).

The less competitive (smaller-sized) male decapod crustaceans tend to avoid direct agonistic encounters with larger males (Clark 1997, Ra'anán & Sagi 1985) and they adopt alternative mating strategies, such as intercepting females moving to the mating areas (Van Der Meer 1994) or copulating quickly, whereas two dominant males are competing for a receptive female (Clark 1997, Correa et al. 2003). In this study the less competitive males migrated earlier to the mating zones, probably to be able to copulate before the more competitive males arrived.

In other majids such as *Chionoecetes opilio* (Sainte-Marie et al.

2000) and *Inachus phalangium* (Diesel 1990), the sperm masses are stored dorsoventrally in the spermathecae when they are not too full (i.e., the last sperm mass is stored closer to the oviduct). This stratification favors that the sperm of the last male fertilize the brood, and therefore the paternity is attributed to only one male. In both species males used several strategies to promote their own paternity. Males of *C. opilio* invest more sperm in females that had mated previously than in virgin females to displace and isolate the sperm deposited earlier (Rondeau & Sainte-Marie 2001), whereas males of *I. phalangium* displace previously deposited masses by transferring large amounts of seminal plasma, which hardens forming a gel that completely seals off the previously deposited masses (Diesel 1990). All of these strategies favor the paternity of the last male to mate with a female. In our study, the high-quality males (larger and in better physiological condition) would be the last to mate. In *M. brachydactyla*, however, the arrangement of the sperm masses is different than what was observed in the previously mentioned species. When several masses are present, they are arranged parallel to the main axis of the spermathecae, and if the spermathecae are full, the arrangement is not stratified (González-Gurriarán et al. 1998; Freire, unpublished data). Although all of these authors reported some differences in the size of the masses, they were attributed to different storage time or the possibility of having been used in part to fertilize a brood, and not to the existence of sperm competition. Based on these findings, there is no evidence that the last males to mate (those of better quality) have a greater probability of ensuring their paternity. However, the results of this study seem to suggest that high-quality males will inseminate females after these might have received sperm from low-quality males. This would only be a successful strategy if last males have fertilization advantages in *M. brachydactyla*. Future studies are required to examine whether sperm precedence in this species follows the same pattern as suggested for other majid species (i.e., last male precedence). The present results of diverging tactics of males during mating migration also seem to call for this pattern in *M. brachydactyla*.

ACKNOWLEDGMENTS

The author thanks Juan Otero, Skipper of the vessel "Bolvina," Cristina Bernárdez, Paz Sampedro, for their help in fieldwork and Martin Thiel, whose suggestions considerably improved the manuscript. This study was funded by research grants XUGA10301B97 from the Dirección Xeral de Universidades e Investigación, Consellería de Educación e Ordenación Universitaria, Xunta de Galicia, and REN2000-0446MAR funded by the Spanish Ministerio de Ciencia y Tecnología.

EFFECT OF DIFFERENT LEVELS OF DIETARY α -TOCOPHEROL ON OVARIAN MATURATION AND REPRODUCTIVE PERFORMANCE OF BROODSTOCK *LITOPENAEUS VANNAMEI* (BOONE)

SHAOBO DU,¹* CHAOQUN HU,¹ SHIQING CAI,¹ QI SHEN¹ AND SHIXUAN ZHENG²

¹The Key Laboratory of Applied Marine Biology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, 510301, Guangzhou, People's Republic of China; ²Yuehai Feed Limited, 524017, Zhanjiang, People's Republic of China

ABSTRACT Effects of 4 grade levels of dietary α -tocopherol (37.82, 115.64, 349.42 and 522.56 mg kg⁻¹ diet) on ovarian maturation and reproductive performance of broodstock shrimp, *Litopenaeus vannamei* were investigated. The α -tocopherol concentrations in hepatopancreas, ovaries, eggs and muscle of female shrimp increased significantly as dietary α -tocopherol levels increased. Survival, spermatophore weight, sperm count, gonadosomatic index (GSI), hepatosomatic index (HSI), fecundity and egg diameter were not significantly affected by dietary α -tocopherol levels. Average daily spawns, hatching rate and fertilization rate significantly increased as dietary α -tocopherol levels increased. Results of this study confirmed the importance of supplementation of α -tocopherol to broodstock diets fed to *L. vannamei*, and suggested that at least 350 mg α -tocopherol kg⁻¹ of diet was needed to achieve significantly better ovarian maturation and reproductive performance.

KEY WORDS: α -tocopherol, broodstock, *Litopenaeus vannamei*, maturation, reproductive performance

INTRODUCTION

In penaeid shrimp, broodstock nutrition is a key factor influencing sexual maturation, reproductive performance and offspring quality (Harrison 1990). To develop suitably performing formulated diets for shrimp broodstock, understanding nutrition-reproduction interactions and determining the specific nutrient requirements for successful maturation and spawning are necessary.

Vitamin E (tocopherols) is considered to be an essential dietary nutrient for crustaceans (Conklin 1997). Available data have shown that α -tocopherol, the most active form of vitamin E, is the predominant form in shrimp/prawn tissue (Cavalli et al. 2001, Wouters et al. 2001), and DL- α -tocopherol acetate, a stable form of α -tocopherol, is the most commonly used vitamin E supplement in animal feeds (National Research Council 1983). The biological role of α -tocopherol is widely accepted to be a lipophilic antioxidant, protecting membranes of cells and organelles from oxidation by scavenging organic free radicals (Burton & Trabor 1990), an activity which may be especially important during embryonic and larval development. The importance of vitamin E for fish reproduction has long been recognized (Watanabe & Takashima 1977, Watanabe et al. 1985), but the importance of this vitamin in shrimp reproduction has only been recently demonstrated. Alava et al. (1993) reported that a α -tocopherol-deficient diet resulted in retarded gonadal maturation of *Marsupenaeus japonicus*. Chamberlain (1988) found a correlation between the percentage of abnormal sperm and dietary vitamin E deficiency in *L. setiferus*. In a trial using *Fenneropenaeus indicus* spawners, Cahu et al. (1995) demonstrated that hatching percentage increased when dietary α -tocopherol levels increased from 40–350 mg kg⁻¹. In wild female broodstock *L. vannamei*, Wouters et al. (2001) detected an increase in α -tocopherol concentrations in the ovary prior to sexual maturation. All these results suggest that vitamin E plays a critical role in the shrimp maturation process.

Information about the effect of dietary α -tocopherol on ovarian maturation and reproduction of *L. vannamei* is lacking. In a previous study, we successively substituted a natural diet consisting of

50% bloodworm (*Glycera chirori*) and 50% oyster (*Crassostrea rivularis*) with a formulated diet for *L. vannamei* broodstock (Du et al. 2004a). In the current study, this previously successful formulated diet was used as the basal diet, and ROVIMIX E50 (Roche Sunve Vitamins Ltd, Shanghai, P.R. China) was added as a α -tocopherol source to investigate the effect of dietary α -tocopherol on the maturation and reproductive performance of *L. vannamei*. The effect of dietary levels of α -tocopherol on α -tocopherol concentrations in ovaries, hepatopancreas, eggs and muscle was also determined.

MATERIALS AND METHODS

Animals and Treatment

Pond-reared *L. vannamei* breeders were obtained from Dongfang Co. (Zhanjiang, P.R. China). They were held in maturation tanks for 3 wk to acclimate to the experimental conditions and fed the basal diet without any supplement of α -tocopherol acetate (Diet E1). A unisex system as described by Browdy et al. (1996) was used: each of 4 maturation tanks was stocked with 15 females each and each of another 4 maturation tanks with 15 males. They were divided into four groups: E1-E4, each consisting of a male tank and a female tank. After acclimation, female shrimp were unilaterally eyestalk-ablated with a pair of flamed tweezers to enhance the rate of ovarian maturation. To identify each female within the same group, part of the telson was cut with the exception of five females and latter sampled to test gonadosomatic index (GSI) and hepatosomatic index (HSI). The duration of the post-ablation phase of the experiment was 50 days, during which, broodstock shrimp representing treatment E1-E4 were fed diets E1-E4, respectively. All treatments were randomly assigned to the maturation tanks.

The maturation tanks were rectangular-shaped cement tanks (2 × 3 m², 55 cm water depth) in which sand-filtered and UV-treated seawater was exchanged at a rate of 200% daily. The physicochemical parameters of the water were: mean temperature, 28.5 ± 1°C; mean salinity, 30 ± 0.5 mg L⁻¹; mean pH, 8.2 ± 0.1; photoperiod, 12 hr light/12 hr dark; and light intensity, 200 lx. Under these conditions, the level of dissolved oxygen remained

*Corresponding author. E-mail: scsio.du@gmail.com

close to saturation; 6.2 g m^{-3} , and ammonia, nitrate and nitrite levels did not exceed 0.03, 0.01 and 0.25 mg L^{-1} , respectively.

Diets and Feeding

Ingredient composition of the basal diet is presented in Table 1. The α -tocopherol source used was Roche ROVIMIX E50, an α -tocopheryl acetate containing $500 \text{ mg } \alpha$ -tocopherol g^{-1} . ROVIMIX E50 was added at different levels, compensated by appropriate additions of carboxy methylcellulose as filler (Table 2). Levels of α -tocopherol added in the dietary treatment were 0, 100, 300 and 500 mg/kg . To prepare the diets, all dried ingredients were smashed and sieved, and then thoroughly mixed with 35% (w/w) water. The resulting stiff dough was pelleted with a mincer with a 3-mm die, and dried at room temperature. The dried "spaghetti like" strands were then crumbled to about 5-mm long pieces and kept in sealed plastic bags at -20°C until use. Shrimp were fed at a daily rate of 5% of the tank biomass (wet weight), proportionately divided over 4 times daily (8:00, 11:00, 14:00 and 18:00). Uneaten food was collected daily.

Broodstock Maturation and Spawning

After unilateral-ablation, females were visually examined for ovarian maturation stages each day at 20:00 according to Wouters et al. (2001). When the majority of the females showed some degree of ovarian maturation, and just before the first mature female with intact telsons was ready to spawn, all females with intact telsons from each treatment were weighed and dissected to determine the gonadosomatic index ($\text{GSI} = 100 \times \text{gonad weight} / \text{total body weight}$) and hepatosomatic index ($\text{HSI} = 100 \times \text{hepatopancreas weight} / \text{total body weight}$).

TABLE 1.

Ingredients and proximate biochemical composition of the basal diet

Ingredients	Weight (g kg^{-1} diet)
Fish meal (CIPSSA, Puerto Montt, Peru)	340
Oyster (<i>Crassostrea rivularis</i>) meal	200
Bloodworm (<i>Glycera chironi</i>) meal	100
Alpha starch§	206.714
Shrimp head meal (50% CP)§	50
Cod liver oil§	40
Soybean lecithin§	15
$\text{Ca}(\text{H}_2\text{PO}_3)_2 \cdot \text{H}_2\text{O}$	10
Cholesterol	5
Sodium alginate	20
Vitamin C (Stay C-35)†	2,286
Vitamin mix*	10
Proximate biochemical composition	(%)
Moisture	6.01 ± 0.18
Ash¶	15.58 ± 0.25
Crude protein¶	49.66 ± 0.82
Total lipid¶	12.14 ± 0.49

§ Alpha starch, shrimp head meal, soybean lecithin and cod liver oil were supplied by Yuehai Feed Co Ltd, China.

† Stay C-35 (Roche Sunve Vitamins Ltd., Shanghai), mainly monophosphate, containing $350 \text{ mg L-ascorbic acid g}^{-1}$.

* Vitamin composition (mg/IU kg^{-1} diet): vitamin A palmitate $100\,000 \text{ IU}$; vitamin D_3 $10\,000 \text{ IU}$; biotin 7 mg ; ascorbic acid 800 mg ; meso-inositol 800 mg ; nicotinic 300 mg ; Ca-pantothenate 600 mg ; pyridoxine HCl 100 mg ; riboflavin 120 mg ; thiamin HCl 50 mg ; folic acid 13 mg ; cyanocobalamin 1 mg ; menadione bisulfite 60 mg ; choline chloride $2,000 \text{ mg}$.

¶ Ash, protein and lipid content was calculated based on dry matter.

TABLE 2.

Levels of α -tocopherol acetate supplemented to the experimental diets

Variable Ingredients	Diets			
	E1	E2	E3	E4
Carboxymethylcellulose (mg kg^{-1} diet)	1000	800	400	0
α -tocopherol acetate (mg kg^{-1} diet)*	0	200	600	1000
α -tocopherol equivalent (mg kg^{-1} diet)	0	100	300	500

* ROVIMIX E-50 (Roche Sunve Vitamins Ltd., Shanghai), containing $500 \text{ mg } \alpha$ -tocopherol g^{-1} .

During the postablation period, the remaining females were examined daily and those with mature ovaries were transferred to tanks containing the corresponding group of males to mate. Each mature female with an attached spermatophore was placed into an individual 120-L spawning tank. In the next morning, spawns were examined and shrimp were returned to their respective maturation tanks. Fecundity (number of eggs per spawn) was estimated by counting three 50-mL samples of water in the spawning tank after vigorous mixing to ensure a homogenous suspension of eggs. Fertilization rate, based on the presence of a double membrane and/or embryonic development in eggs, was determined from examination of three 50-mL samples from each spawn. A sample of 10,000 eggs from each spawn was individually incubated at 29°C to estimate the hatching rate (% nauplii/fertilized eggs). Hatching rate was calculated by counting the number of nauplii per spawn sample through collection by positive phototropism. Egg diameter was estimated by measuring 50 eggs from each spawn with a light microscope and micrometer. About 100 mg of eggs were sieved from each spawn and immediately rinsed in freshwater and stored at -70°C . Egg samples from the same group of females were pooled to obtain sufficient tissue for α -tocopherol analysis. At the end of the experiment, five stage II females from each group were dissected. Hepatopancreata, ovaries and muscle of females from each dietary treatment were pooled and stored at -70°C for latter α -tocopherol analysis. Spermatophore quality was based on sperm count and spermatophore weight according to Alfaro & Lozano (1993). At the end of the experimental period, five males with mature spermatophores from each treatment group were selected, and their spermatophores were extruded by gently pressing around the coxae of the fifth pair of pereopods. Both sides of the compound spermatophore were weighed to the nearest 1 mg. The quantities of sperm were determined by homogenizing the compound spermatophore in a calcium-free solution and by counting the sperm cells under light microscopy.

Biochemical Analysis

Triplicate biochemical analysis of the basal diet was conducted according to the following standard procedures (AOAC 1990). Moisture was determined by oven drying to constant weight at 105°C . Crude protein ($\text{N} \times 6.25$) was derived from Kjeldahl nitrogen analysis. Ash was determined as the residue after muffle furnace ignition at 550°C for 6 h. Total lipid content was determined after Soxhlet extraction with petroleum ether at 60°C for 8 h.

Tissue α -tocopherol content was determined triplicately with HPLC (HP 1100) using methods modified slightly from those of Alava et al. (1993) and Huo et al. (1999). The analytical condition of HPLC was as follows: detection at UV-284 nm; column tem-

perature, 35°C; eluent, methanol-water (96: 4, v/v); flow speed, 1.0 mL/min. α -tocopherol was extracted from samples by the method of Huo et al. (1996). Alpha-tocopherol was extracted from 0.2 g of freeze-dried samples by homogenization in 2 mL of methanol containing butylhydroxytoluene (1 mg/mL). The homogenates were clarified by centrifugation and passed through a 0.45 μ m-pore-size syringe filter (SIGMA). Twenty microliters of the filtrate were introduced into the HPLC injection port. Alpha-tocopherol (95%, SIGMA) was used as standard.

Statistical Analyses

An individually marked female within the same treatment group was considered to be an experimental unit for statistical analysis. This is the most commonly used statistical procedure applied in shrimp reproduction trials (Wouters et al. 2002). Data of GSI, HSI, fecundity, daily spawns per female, egg diameter, fertilization rate and hatching rate from each group were subjected to 1-way ANOVA and subsequent Duncan's multiple-range test to determine difference in means. Prior to analysis, Levene's test for homogeneity of variances was used to verify the assumptions for further analysis. There was no need to transform data. A regression analysis was used to determine if a relationship existed between either fecundity, egg diameter, fertilization rate or hatching rate and the spawn order. No relationships were detected, and spawn order was not considered to be a factor to include in the evaluation. An alpha level for all tests was set at 0.05. Statistical analysis was performed using Systat package (Systat Software Inc. 1996).

RESULTS

Average initial weight of female and male broodstock was 51.4 ± 3.56 g and 48.02 ± 5.39 g, respectively. Survival of male and female broodstock within the different groups is presented in Table 3. A slight loss, probably induced by manipulation, occurred in all groups during the experiment; therefore, number of spawns was calculated based on per female per day.

Alpha-tocopherol concentrations in hepatopancreata, ovaries, eggs and muscle of female *L. vannamei*, as well as in the experimental diets are presented in Table 4. The actual α -tocopherol concentrations in the experimental diets were higher than the supplemented amounts because the ingredients of the basal diet contained 37.82 mg kg^{-1} α -tocopherol. In the present study, female shrimp sampled to determine α -tocopherol content were at

maturation stage II, with mean GSI values of 1.45 ± 0.07 for group E1, 1.52 ± 0.05 for group E2, 1.60 ± 0.04 for group E3 and 1.63 ± 0.07 for group E4, respectively. Results showed that the α -tocopherol content of tissue was significantly affected by dietary α -tocopherol levels. Concentrations of α -tocopherol in the ovaries and eggs were higher than those in the hepatopancreata. Levels of α -tocopherol in the ovaries of shrimp in groups E3 and E4 ($186.43 \text{ mg kg}^{-1}$ and $207.37 \text{ mg kg}^{-1}$) were significantly higher than those of shrimp in groups E2 (93.77 mg kg^{-1}) and E1 (75.04 mg kg^{-1}). Alpha-tocopherol concentrations in the hepatopancreata and eggs increased significantly as levels of dietary α -tocopherol increased, and generally values for each of the groups differed significantly from one another. Supplementation of α -tocopherol acetate also increased the α -tocopherol content in muscle. The α -tocopherol concentration in muscle of shrimp from group E2 (50.6 mg kg^{-1}) was significantly higher than that of shrimp from group E1 (24.5 mg kg^{-1}), but was significantly lower than that of either group E3 (89.3 mg kg^{-1}) or group E4 (104.6 mg kg^{-1}).

Ovarian maturation and reproductive performance of shrimp representing the different treatments are presented in Table 3. For male broodstock *L. vannamei*, spermatophore weight and sperm count were not significantly different. As dietary α -tocopherol levels increased, GSI and HSI values of female broodstock did not differ significantly. Average daily spawns per female were significantly affected by dietary α -tocopherol levels. Females in treatment E3 gave the highest daily spawns, significantly higher than those in treatments E2 and E1. Daily spawns of females in treatments E3 and E4 were not significantly different.

Fecundity and egg diameter were not significantly different among the dietary treatments. Supplementation of α -tocopherol acetate to the basal diet significantly increased the fertilization rates for treatments E3 (59.6%) and group E4 (61.45%) relative to treatments E2 (51.3%) and E1 (45.4%). The hatching rates for treatments E1 (31.2%) and E2 (34.2%) were significantly lower than those for treatments E3 and E4.

DISCUSSION

The current study showed that α -tocopherol content in the basal diet (37.82 mg kg^{-1}) was sufficient to maintain normal survival, successive maturation and spawns of *L. vannamei*; however, to achieve significantly higher daily spawns, fertilization rates and

hatching rates, supplementation of α -tocopherol to broodstock diets is essential.

The increase in α -tocopherol concentrations in eggs, hepatopancreata and ovaries of female *L. vannamei* as dietary α -tocopherol levels increased was similar to the results obtained by Cahu et al. (1995). In their study, α -tocopherol concentration in eggs of *Fen. indicus* increased from 177 mg kg⁻¹ to 587 mg kg⁻¹ as dietary α -tocopherol levels increased from 82 mg kg⁻¹ to 354 mg kg⁻¹. The beneficial action of α -tocopherol is most probably related to its antioxidant properties. The α -tocopherol accumulated in the egg yolk acts as a natural antioxidant (Harrison 1997), and may be especially important for the embryonic and larval development. This positive effect has been verified in the study of Cahu et al. (1995), who showed that hatching rate of *Fen. indicus* increased significantly, from 28% to 55%, when egg α -tocopherol concentration increased from 177 mg kg⁻¹ to 587 mg kg⁻¹. In the present study, elevation of α -tocopherol content in ovaries and eggs relative to dietary supplementation might also suggest its positive effect on ovarian maturation and embryonic development. Wouters et al. (2001) found that α -tocopherol concentrations in ovaries of wild *L. vannamei* increased as sexual maturation proceeded, and suggested that this vitamin has a critical role in advancing the shrimp maturation process. Similarly, Cavalli et al. (2001) detected a sharp increase of α -tocopherol in the ovaries of wild *Macrobrachium rosenbergii* during the initial gonadal development from stage I to III. They also suggested the dietary importance of this vitamin to serve as a major antioxidant agent during ovarian maturation. For penaeid shrimp, hepatopancreas and muscle tissues are the main storage organs for α -tocopherol (Cahu et al. 1995). The lower concentration assayed in muscle of females of groups E1 and E2 might indicate that this vitamin was transported from muscle to ovary during vitellogenesis, as was reported in *Fen. indicus* (Cahu et al. 1995) and *Mar. japonicus* (Alava et al. 1993).

Little information on the effect of broodstock nutrition on reproductive performance of male broodstock shrimp is available. In the present study, lack of a significant change in spermatophore weight and sperm count as levels of dietary α -tocopherol increased

suggests that further studies need to be conducted to evaluate the effect of higher dietary α -tocopherol levels on the spermatophore quality of male broodstock *L. vannamei*. GSI and HSI indicate the accumulation of nutrients in the ovaries and hepatopancreata of female *L. vannamei*. Similar to a previous study conducted by Du et al. (2004b), the period between eyestalk ablation and the first maturation of females with intact telsons was only 6 days, and the similar values of GSI and HSI might be attributed to the relatively short period of time. In the present study, females fed diets containing 349.42 and 522.56 mg kg⁻¹ α -tocopherol gave significantly higher daily spawns, suggesting that at least 349.42 mg kg⁻¹ of α -tocopherol in broodstock diet was needed to significantly enhance the ovarian maturation of female *L. vannamei*. Alava et al. (1993) also demonstrated the positive effect of α -tocopherol on ovarian maturation, and showed that 482 mg kg⁻¹ α -tocopherol in the broodstock diet was necessary to cause ovarian maturation of *Mar. japonicus*.

Alpha-tocopherol is also an important factor to improve the fertilization and hatching performance of shrimp eggs. In the study conducted by Cahu et al. (1995), hatching rate increased significantly, from 28% to 55%, when dietary α -tocopherol levels increased from 82 mg kg⁻¹ to 354 mg kg⁻¹. The positive effect of high dietary α -tocopherol content on the improvement of egg hatchability was concluded. Similarly, egg hatching rate was also positively correlated with α -tocopherol concentration of eggs in the studies conducted by Cahu et al. (1991, 1993). Results of this study showed that diets containing α -tocopherol levels of at least 349.42 mg kg⁻¹ and fed to *L. vannamei* broodstock could significantly increase the fertilization rate and hatching rate of eggs.

INFERRING SHRIMP (*PANDALUS BOREALIS*) GROWTH CHARACTERISTICS FROM LIFE HISTORY STAGE STRUCTURE ANALYSIS

PETER A. KOELLER*

Department of Fisheries and Oceans, Bedford Institute of Oceanography, P.O. Box 1006,
Dartmouth, Canada

ABSTRACT An aged-based population model was used to simulate shrimp (*Pandalus borealis* Kroyer) age and stage structures at different growth rates and the results compared with stage structures of populations with known growth rates. Both simulations and field data indicate that different growth rates result in characteristic stage structures, which can be used to infer spatial and temporal differences in growth rates. It is concluded that the mean carapace lengths of all life history stages ordered chronologically (stage structure), contains more information on growth characteristics than the carapace length of individual stages (e.g., length at sex change, L_{50}) alone. In the absence of growth information, based on direct ageing methods, it is recommended that the complete stage structure be used when inferring growth characteristics from carapace length data. In addition to allowing specific spatial and temporal comparisons of growth rates, stage structure analysis allowed inference of the following growth characteristics, including: growth rates are highly site specific and sensitive to environmental conditions such as food availability and temperatures; environmental influences on growth rates tend to affect all size categories (i.e., stages and ages) simultaneously and without time lags; the “invariant” relationship between L_{50} and maximum size (L_{max}) is not unique to these stages and simply a consequence of environmental influences on the growth rate of all stages simultaneously; length at sex change is directly related to growth/metabolic rates; length and age at sex change are highly flexible, occurring at the age and size a shrimp happens to be when growth/metabolic rates determine sex change. The usefulness of stage structure analysis as an indicator of ecosystem change is discussed in light of the results.

KEY WORDS: northern shrimp, *Pandalus borealis*, growth, sex change, life history stage, ecosystem indicators

INTRODUCTION

Measuring the growth of crustaceans is limited by their lack of hard parts that could be used to directly determine age with confidence. Length-based methods, such as modal analysis (e.g., MacDonald & Pitcher 1979), can be used to determine length-at-age of crustaceans *in lieu* of more direct determinations. However, these methods are fraught with inaccuracies, primarily because modes become more difficult to distinguish and associate with a particular age or year class as age and length increase. In northern shrimp *Pandalus borealis* (hereafter also called shrimp), longevity can vary from 4–8 y or more depending on locality and time (Shumway et al. 1985, Bergström 2000), yet for many stocks only ages 2 and 3 are most consistently identifiable as distinct modes in length frequencies. This has seriously limited the development of quantitative, age-based assessment methods and research on spatial or temporal variations in growth rates (Frechette & Parsons 1982).

Carapace lengths at sex transition, and other life history stages, have been used to infer growth characteristics for *P. borealis*. For example, Koeller et al. (2003) concluded that on the Scotian Shelf the size at which these protandric hermaphrodites change sex from male to female (L_{50}), and their maximum size (L_{max}), are largely determined by growth rate. Wieland (2004) and Koeller et al. (2006) used size at sex transition and of other stages to infer temporal changes in growth rate off West Greenland and on the Newfoundland-Labrador Shelf. Older age classes are seldom identifiable by distinct modes, but they can often be differentiated in length-frequency analyses by separating female life history stages. Thus, distinguishing between primiparous females (about to spawn for the first time) and multiparous females (spawned before) using the presence or absence of sternal spines often allows identification of two female age classes (Frechette & Parsons 1982). Although the youngest age classes may be distinguishable by the presence of distinct modes, and the oldest by sternal spines, intermediate male year classes immediately before sex change are often

indistinguishable such that it is difficult to relate size at sex change to growth rate. Consequently, an increase in the length at sex change could be because of an increase or a decrease in growth rate, depending on whether longevity, specifically the number of male age classes has, respectively, remained the same or has increased.

Another problem with relating L_{50} to growth is the possibility that L_{50} is determined by factors other than growth, such as sex ratio and social interactions, associated with the “sex allocation theory” of Charnov (1982). Another theory by the same author advocates that the ratio of L_{50}/L_{max} in *P. borealis* is a biological invariant (Charnov 1993, Charnov & Skúladóttir 2000) that provides insight into the evolutionary mechanisms behind sex change in a wide variety of species. In addition to being somewhat contradictory with the former (Koeller et al. 2003), the latter theory has recently come under attack for fundamental analytical reasons (Cipriani & Collin 2005, Nee et al. 2005, de Jong 2005).

This paper takes a more comprehensive look at the use of shrimp life-history stage length statistics in the inference of growth characteristics and discusses the results in relation to current theories on the factors controlling sex change. The approach taken is to compare different growth rates and the “stage structures” they generate using an age-based population model, and to compare the simulated stage structures with those from populations having known growth characteristics. The main hypothesis is that the shape of the curve created by joining the means of life-history stage carapace lengths ordered chronologically (i.e., the stage structure as opposed to the age structure of the population) can provide more information on growth characteristics and other aspects of shrimp biology than that produced when stages are considered in isolation, or in combination with only one other stage, such as the ratio of L_{50}/L_{max} .

METHODS

Calculation of Stage Statistics

Note that the term “stage length” used throughout refers to the mean carapace length of that stage and not the stage duration. The

*E-mail: koellerp@mar.dfo-mpo.gc.ca

mean lengths of six life history stages were included in the analysis:

L_{min} —the carapace length of the smallest shrimp in a sample, averaged over a number of samples. This is the size at which shrimp first assume a more benthic life style and begin to be retained by bottom trawls. This metric must be strongly influenced by mesh size and other gear selectivity factors. However, under certain conditions L_{min} may also be indicative of growth between hatching and the time of capture. An important condition is that the gear captures some of the smallest (i.e., in the youngest year class) individuals in the population and that the subsample (of the total catch) size is large enough to measure at least one of these. Shrimp trawls usually do capture (and samples show the presence of some, although not many) very small individuals (<10 mm). On the Scotian Shelf, shrimp caught with special juvenile sampling gear in the June survey are ~1.25 y old (~8 mm average carapace length) and have been on the bottom for at least 8 mo (Koeller et al. 2005). The length distribution is normal with a standard deviation of ~1.5, consequently the largest members of the first year class will be several millimeters longer than their mean size, and should be present in many trawl samples. There is usually little or no overlap between the lengths of ages 1 and 2 (mean size ~14mm), so it is likely that shrimp <10 mm are from the first year class, at least on the Scotian Shelf. Two other conditions that are necessary to relate L_{min} to growth for comparison between areas and times is that selectivity should not change, and that samples should be collected at the same time of year. These conditions are usually met within a survey series, but not between series using different gear types, cod-end mesh sizes or survey times, or for samples collected from commercial fishery catches, which are obtained from different vessel and trawl gear types.

L_m —the average size of males in a sample, averaged over a number of samples. In addition to growth, this statistic will be influenced by other population dynamics including recruitment and mortality. For example, in a population of four male age classes where the three youngest had average recruitment and the oldest strong recruitment, L_m will be larger than if recruitment had been the same for all year classes. Note that shrimp generally mature as males when quite small—usually (and in this paper) no distinction is made between mature and immature males.

L_{50} —the length at which half of the shrimp in a sample are female, averaged over a number of samples. This statistic was estimated by fitting a logistic model to cumulative percent (female) length-frequencies of individual samples and estimating the length at which 50% of the shrimp were female as described in Skúladóttir (1998). All model fitting was carried out using the *glm* function in S-PLUS Version 6.2 (Insightful Corp.) with the logit function link to the equation:

$$y = 1/(1 + e^{-(a+bx)})$$

where y is the estimated proportion of females, x is the carapace length, a is the regression coefficient and b is the steepness coefficient of the logistic curve. This statistic can also be influenced by changes in population dynamics. All other factors like growth rate being equal, L_{50} will be larger if the last male year class is more abundant than the others. It will decrease if the population of first year (primiparous) females is larger, or their mortality is less than average. Sampling time, or annual variability in the time and speed at which sex change in the population occurs may also affect this statistic, for example, if a larger percentage of males than usual have changed sex before the survey period then the average size at

sex change will be lower, and vice-versa. The methods of calculation used by different workers may lead to different results depending on which component of the female population is used to calculate the percentage of females. In this paper it is calculated using primiparous females wherever possible, because it is these females that are changing sex during the sampling year. However, in Newfoundland the survey is conducted in November-December at a time when only a small number of, or no, primiparous females, which have not become ovigerous are present. In this area L_{50} was calculated from the percentage of total females. In addition to the above factors, L_{50} may also be influenced by seasonal sampling times. However, variation because of this factor are minimized by identifying transitional (undergoing sex change) individuals and including them in the female category when sampling occurs during the relatively short (several months) period when shrimp are actively changing sex.

L_{f1} —the average size of primiparous females in a sample, averaged over a number of samples. Primiparous females are identified as females with sternal spines (McCrary 1971). These spines are located in the abdominal area where eggs are brooded and tend to be lost when the female first extrudes eggs. A female with sternal spines has therefore not spawned before and probably belongs to the youngest female age class. In this paper L_{f1} includes shrimp that have been identified as "transitional" (i.e., in the process of changing sex) because this stage is relatively short and all shrimp in this category will join the primiparous population that year.

L_{f2} —the average size of multiparous females in the sample, averaged over a number of samples. Multiparous females are identified as females without sternal spines, and so have spawned before. Because natural mortality is high after two years as females, most females in this category will usually be second year females. However, a certain number of older females are likely present, especially if the length-frequency distribution of this stage is skewed to the right. Note that the time of sampling within the annual spawning cycle determines if L_{f1} and L_{f2} can be distinguished from each other. Because most L_{f1} females will have spawned by fall, a survey at this time will usually not be able to distinguish these stages (e.g., the Newfoundland survey series). Moreover, commercial samples in this study do not distinguish between the two stages of females even if both are present. In these cases mean female size is calculated from all females combined and is designated as L_f .

L_{max} —the largest shrimp in a sample, averaged over a number of samples. This can be taken as a proxy for L_x in the Von Bertalanffy growth equation. Unlike L_{min} , selectivity should have little effect on this parameter, because most shrimp in this size range are likely to be retained by the fishing gear. However, as with L_{min} , sample size (number of shrimp per sample) may be a factor. For example, a heavily-fished population will have fewer of the largest shrimp. Although some will still be present in the population, a larger sample size may be required to ensure they are also present in the sample. The largest shrimp are likely older than the second female year class, particularly if the female length frequency is right-skewed.

Simulations

A simple age-based model was used to simulate shrimp growth and the population length, age and stage structure for the areas under consideration, using a range of growth rates and longevities

encompassing those reported in the literature for the areas under consideration (Table 1). The number of male age classes was varied between 2 and 5, which encompasses the number of male age classes in the Gulf of Maine (2–3), the Scotian Shelf (3–4) and the southern Newfoundland Shelf (4–5). It was assumed that all populations had only two female age classes corresponding to the common primiparous and multiparous designations (L_{t1} and L_{t2} above). Although there may be more than two female age classes present in the population, in general mortality is considered to be high after the second year as females and relatively few survive a third year. The length structure for each age class was generated with a normal distribution function using parametric standard deviations (sigmas) similar to those seen in shrimp modal analyses with the MIX computer program (Macdonald & Pitcher 1979). Sigmas ranged between 1 and 1.6 and were increased by increments of 0.1 units/year with increasing age, held constant for all simulations. Modal lengths of age classes (i.e., growth) were determined by a von Bertalanffy growth function using parameters determined from available length at age data for specific stocks. Generally, lengths at age and growth for *P. borealis* stocks are determined with modal analysis. This is best done by an experienced analyst having local knowledge of the stock. Lengths-at-age information for the three stocks (Table 1) examined here were therefore obtained from stock assessment documents or other sources as follows: Gulf of Maine, Anon. (2004); Scotian Shelf, Koeller et al. (2005); Newfoundland Labrador Shelf, Orr et al. (2003); Parsons et al. (1986, 1989). Year-class strengths were held constant and equal for all age classes unless the sensitivity to changes in year-class strength was being tested. Selectivities were determined by a logistic curve using the same equation described under L_{50} above, but where y is the selectivity factor, $a = 0.5$ and $b = 15$. This provided a typical sigmoid cumulative selectivity curve resulting in a 50% retention length of 15 mm with a length range of 4.4–30 mm. Because it was assumed that all ages and stages were represented in the population (sample), variations of the selectivity function, while changing the relative abundance of ages and stages considerably, had little effect on average age and stage lengths. Consequently selectivity was held constant for all simulations. The total mortality factor (constant for all simulations) was set at a survival rate of 0.5 ($Z = 0.70$) (i.e., half of the population died each year until the second year as females) when mortality was total. This is considered a reasonable rate of natural mortality (M) for this species in stock assessments and was used as

total mortality, because fishing mortality or other impacts other than selectivity were not simulated. The above-mentioned combination of selectivity and mortality resulted in a typical survey length frequency distribution. Sex change was assumed to occur within one year with all males from the last male year class changing to primiparous females. Stage statistics (mean lengths for L_{min} , L_m , L_{50} , L_{t1} , L_{t2} and L_{max}) were then calculated as population parameters (i.e., sampling was not simulated).

Survey Data

Length statistics were examined from three stratified random shrimp survey series used in the stock assessments of three distinct stocks, including the Gulf of Maine (Anon 2004), the eastern Scotian Shelf (Koeller et al. 2005) and the Newfoundland Shelf (Orr et al. 2003). Survey methods, which are provided in the publications above, differ somewhat between these regions, but within each series all use standardized survey tow lengths and shrimp trawls. Within each series, surveys are conducted at the same time of year. All surveys use the same carapace length measurement technique (oblique length from the posterior edge of the eye socket to the posterior middorsal edge of the carapace) and criteria for distinguishing life history stages (i.e., between males and females, Allen 1959) and between primiparous and multiparous females (McCrary 1971). An important difference between methodologies is survey time—the Gulf of Maine and the Scotian Shelf surveys are conducted during spring or early summer (May to June), whereas Newfoundland surveys are conducted during fall winter (November–January). Because the population's stage structure changes seasonally, this must be taken into consideration when comparing stage structures between areas, for example the lack of primiparous females in the Newfoundland series described earlier. Because some survey catches can be small and sample carapace lengths inaccurate only samples with at least 200 shrimp, including both males and females, were included in the analysis. After filtering the data according to this criterion a total of about 5,500 survey samples from the three survey series remained available for analysis (Table 2). The locations of the primary areas considered in this paper are shown in Figure 1.

Commercial Fisheries Data

In addition to survey samples, a large number (>20,000) of commercial samples were collected between 1990 and 2002 from 47°N (off Newfoundland) to 67°N (Davis Strait). These were collected by trained observers, with onboard analyses similar to survey samples, including carapace length measurements to the nearest 1/10 mm, and determination of life history stage, although the latter was limited to identification of males and females only (i.e., transitionals, primiparous and multiparous females were not distinguished). The large number of samples allowed more detailed analyses of stage-length statistics, particularly the relationship between stages, and between stage size and environmental parameters. The total number of samples that were available for analysis by area, year and data source is given in Table 2.

RESULTS

Growth Simulations

In the first set of simulations (Fig. 2A), growth rates were held constant, but longevity varied from 4–7 y (2–5 male age classes, 2 female age classes). The most notable result is that the shape of

the stage structure changed significantly with the number of male age classes. The shortest longevity (lowest number of male age classes) had the straightest stage structure, whereas the longest had the greatest curvature characterized by a rapid increase in length to a peak at L_{50} , a decrease at the first female stage, followed by an increase to L_{max} . Intermediate longevities had intermediate degrees of curvature to their stage structures. With growth rates held constant, longer longevities and greater curvatures also have correspondingly larger stage lengths for all stages except L_{min} . Note that this simulation is intended to be illustrative rather than realistic, because one would expect increased longevities to be associated with decreased growth rates.

In the second simulation (Fig. 2B) longevities were held constant at the 6 age classes typical for many shrimp stocks (4 male, 2 female) but growth rates varied. In these simulations stage structure (curve shape) changed little. All exhibited the rapid increase in length to L_{50} , decreased rate of increase to the female stages and more rapid increase to L_{max} noted in the previous simulation. All stage lengths, including L_{min} , increased with growth rate.

A third set of simulations (Fig. 2C) used typical growth rates and longevities reported for the three study regions (Table 1). The fastest reported growth rate and shortest longevity (only 2 male age classes) is from the Gulf of Maine. The Scotian Shelf simulation used 4 and the Newfoundland-Labrador Shelf 4 and 5 male age classes. Longevities reported for the Newfoundland-Labrador Shelf vary considerably from 4–6 male age classes, with 4 and 5 being the most common (Parsons et al. 1986, 1989). Growth rates

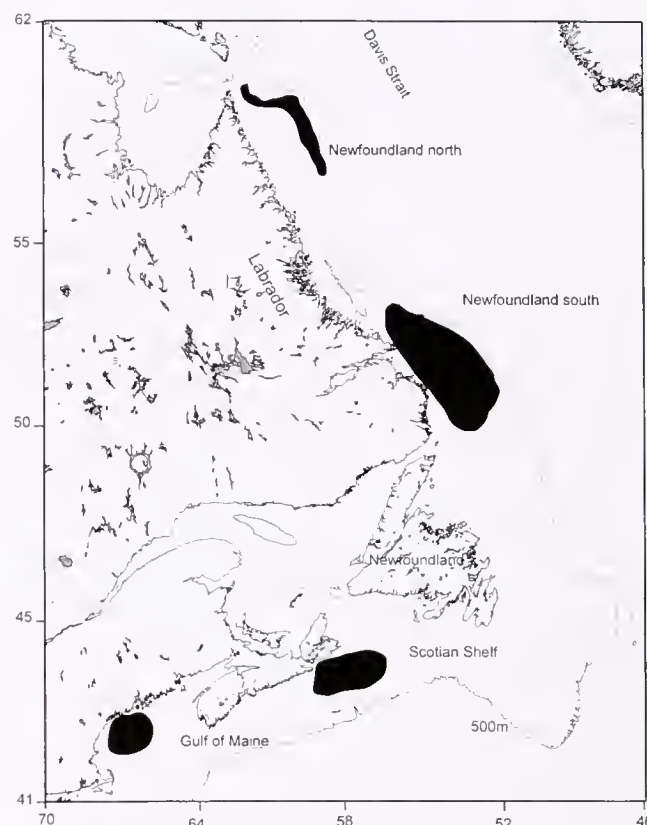

Figure 1. Map showing the 3 main study areas (Gulf of Maine, Scotian Shelf and the Newfoundland-Labrador Shelf). The latter is divided into northern and southern parts.

reported for the Scotian Shelf are somewhat faster than those for the Newfoundland Shelf. As would be expected from Figure 2A, the simulation using the short longevities reported from the Gulf of Maine showed the straightest stage structure. Stage lengths are about the same as for other areas, not smaller as would be expected if growth rates were the same. Apparently the much higher growth rate in the Gulf of Maine compensated for the shorter longevity, particularly in the three oldest stages, which were considerably larger than those in the other areas. Because of its slower growth rate, the Newfoundland-Labrador curve with only four male age classes fell well below that of the Scotian Shelf. When five male year classes are used for the Newfoundland-Labrador Shelf the curves for these two areas are indistinguishable despite their being based on different longevities. The increase in stage lengths expected with increased longevity alone, as in Figure 2A, compensated for the decrease in stage length expected from lower growth rate alone, as in Figure 2B.

A final set of simulations (Fig. 2D) explored the effects of a large recruitment event in which a strong year class ($100 \times$ average recruitment) moves through the population. Longevities and growth rates were held constant, using values characteristic for the Gulf of Maine, whose shrimp population size and fishery are highly dependent on such events. The effects of the strong year class changed stage structure considerably in the younger stages, including L_{50} . On the other hand, L_{min} , which in this case was determined by selectivity alone, was not changed. The appearance of a large number of young males decreased L_m in Year 1. In Year 2 the large number of males about to change sex increased the

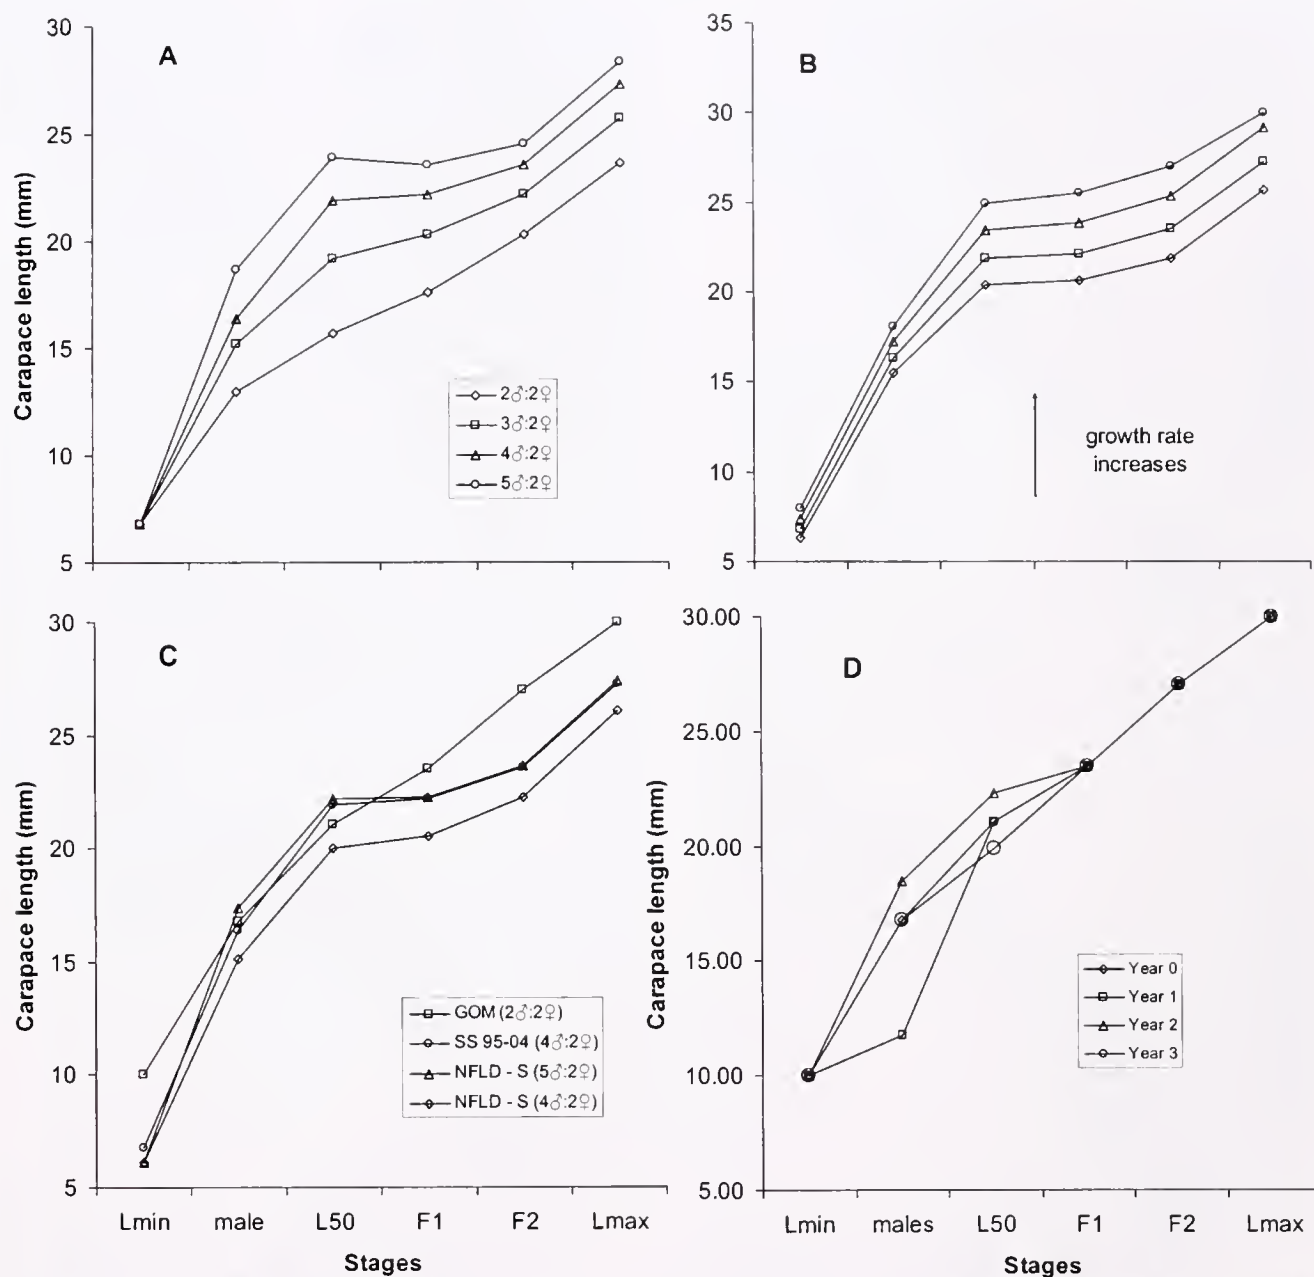

Figure 2. Simulation results including (A) constant growth rates but longevities varying from 2–5 male year classes; (B) constant longevities (4 male and 2 female age classes) but varying growth rates; (C) observed growth rates and longevities for the Gulf of Maine, Scotian Shelf and southern Newfoundland Shelf. The latter includes curves for 4 and 5 male age classes. (D) simulated annual stage lengths where a strong year class ($100 \times$ average recruitment) appears at Year 1 and moves through the population over the next 2 y. The population has two male and two female age classes as in the Gulf of Maine.

estimate of L_{50} because more females are needed to reach the 50% point, which are found farther along the ascending limb (at longer carapace lengths) of the female frequency distribution. In Year 3 the strong year class was in its first year as females, and L_{50} had decreased almost back to its pre-event (Year 0) value. Stage sizes after L_{50} were unchanged during all years.

Survey Data

The age and stage structures for two survey years (1995 and 2000) where both are available in all three areas are shown in Figure 3. Both years show the exceptional growth rate and shorter

longevity usually exhibited by Gulf of Maine shrimp. Despite the large difference in growth rates, shrimp on the Scotian Shelf and the Gulf of Maine change sex at about the same length (~22–23 mm) and achieve similar maximum lengths of 29–30 mm (Fig. 3 C, D). However, Gulf of Maine shrimp change sex after only 2 y as males, whereas on the eastern Scotian Shelf there are usually four male year classes. Growth rates on the southern Newfoundland Shelf are somewhat slower than on the Scotian Shelf, although longevities appear to be similar. Sizes at sex change (~21–22 mm) and maximum size (25 mm) are considerably less on the Newfoundland Shelf compared with those on the Scotian Shelf.

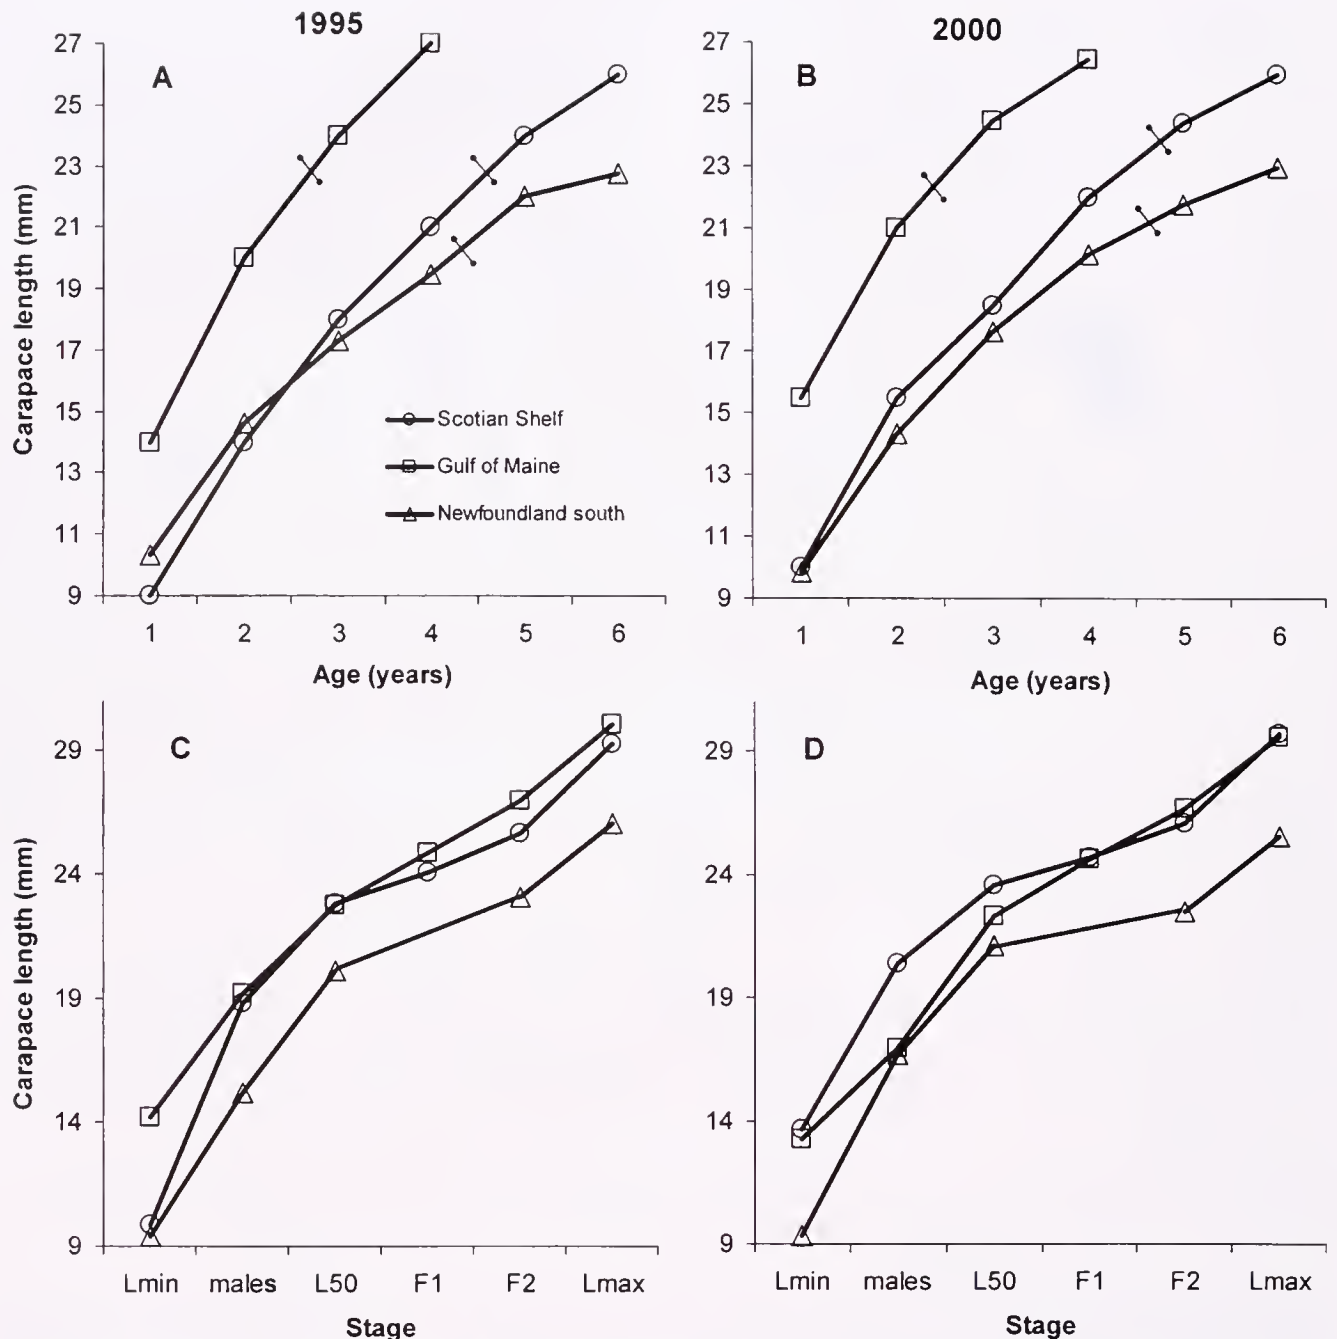

Figure 3. Carapace lengths at age for the Gulf of Maine, Scotian Shelf and southern Newfoundland-Labrador Shelf survey data for 1995 (A) and 2000 (B) illustrating the main differences in growth characteristics between these areas. The sizes and ages at sex change are indicated by diagonal lines. The corresponding stage structures are shown in C and D.

Growth rates are lower (Fig. 3A, B) and stage lengths are shorter (Fig. 3C, D) on the Newfoundland-Labrador Shelf compared with those for Scotian Shelf shrimp during both years. This suggests that longevity for these two areas are the same (i.e., 4 male age classes) because simulations indicate that a longevity of five male year classes on the Newfoundland-Labrador Shelf versus four on the Scotian Shelf should have resulted in similar stage sizes (Fig. 2 C). The large difference in growth rates between the Gulf of Maine and the other areas is not reflected in the younger (than L_{F1}) stage lengths, which are similar to those on the Scotian

Shelf. This is as expected from the simulation (Fig. 2C) (i.e., the longer longevity on the Scotian Shelf compensated for the slower growth rate) resulting in similar stage sizes. However, the older stages in the Gulf of Maine surveys are also about the same size as on the Scotian Shelf, but these were considerably larger in the simulation. Differences in the shape of the curves defined by survey mean stage sizes in the three areas are consistent with simulations. The Gulf of Maine curves are relatively straight compared with those for the other areas in both years. The consistency of the differences in curve shapes and stage lengths between areas is seen

in Figure 4 where the averages of the annual stage mean lengths are plotted for all survey years since 1995, along with standard deviations.

Figure 5 shows annual differences in stage structures for each of the three areas. The Gulf of Maine (Fig. 5A) has the longest time series of targeted shrimp surveys in the north Atlantic, and exhibited a wide range of stage lengths, 4–6 mm for all stages except L_{\max} , which had a narrower range (2 mm). The shape of the annual stage structures varied widely in this area. Many of the plots for the first 10 years of the series exhibit a greater curvature and longer stage lengths, but some years during this period also have straighter curves and shorter stage lengths than the others (e.g., 1983, 1992). Similarly, many of the annual plots during the last 11 y of the series appear to be straighter than during the previous period, however there is also considerable variability. On the Scotian Shelf (Fig. 5B) the earlier years clearly exhibit a greater curvature and longer stage lengths than the later years, which is opposite to the case for the Gulf of Maine. The Scotian Shelf stage structures more clearly separate into two time periods (i.e., 1982–1988) and 1995–2004.

The Newfoundland-Labrador Shelf survey series is the shortest and has the least consistent spatial coverage of all the three main areas. The time period shown (1996–99, Fig. 5C) includes years when survey data are available in both the northern and southern areas of the shelf and significant decreases in shrimp lengths were observed (Orr et al. 2003, Koeller et al. 2006). In the two early years the curves in the northern area are straighter and all stages, especially L_{\min} and L_m , much longer than those in the south. The greater curvature during the last two years in the north is associated with shorter stage lengths of all stages, but especially of the largest, oldest stages. These decreased greatly to carapace lengths comparable to (1999), or smaller than (1998) in the south.

Figure 5D shows 4 y extracted from Figure 5A during which

Figure 4. Average stage structures in the Gulf of Maine, Scotian Shelf and Newfoundland-Labrador Shelf surveys for years (1995–2003) when survey information was available for all three areas. Error bars represent ± 1 standard deviation.

the large 1982 y class moved through the Gulf of Maine population. The actual stage structure is similar to those for the simulated recruitment event shown in Figure 2D, including the similar L_{\min} (except for 1983), progressively older stage lengths becoming larger in sequence, and convergence of the largest stage sizes. However, this convergence occurred at L_{12} in the surveys versus L_{11} in the simulations.

Commercial Fishery Versus Survey Data

L_{50} carapace lengths are plotted against all other identified stage lengths for all available commercial (20,596) and survey samples (2,158 samples with >200 shrimp/sample) in Figure 6. The slopes of the regressions between L_{50} (dependant) and other stages are all positive and significantly different from 0. The stage structures around the median and the 1st and 3rd quartile hinges of L_{50} within each data set are shown in Figure 7. Commercial stage structures are noticeably straighter than those obtained from survey samples. All commercial stages are significantly larger than survey stages, although the difference is considerably less for L_{50} .

In simple paired correlations the lengths of all stages were usually significantly correlated with all environmental (density, depth), spatial (shrimp fishing areas) and temporal (year and month) factors available for analysis in both data sets i.e., 42 out of 50 (5 factor \times 5 stages \times 2 data sets) correlations significant at $P < 0.05$. Depending on the stage used as the dependant variable, all these factors combined accounted for 32% to 73% and 33% to 40% of the variability in stage size for commercial and survey samples, respectively, in linear multiple regression analysis, although most of this was caused by area and year effects (Table 3). In addition to environmental, spatial or temporal factors, stage lengths were also significantly related to each other (Table 3, Fig. 6). Depending on the stage used in multiple regressions, 53% to 78% and 45% to 68% of the variability of any stage was accounted for by the length of the other stages in commercial and survey samples, respectively. The strength of the relationships between stages tended to decrease with increasing differences in length (Table 4). For example, the relationship between L_{50} in commercial samples was strongest with L_m and L_1 , the next smallest and next largest stage, respectively, and weaker with the smallest and largest stages (i.e., L_{\min} and L_{\max}). Similarly, L_{\min} was correlated most strongly with L_m and less so for the longer (older) stages. Finally, L_{\max} was most strongly correlated with L_1 , and less so for the smaller (younger) stages, including L_{50} . Similar results were found for survey data (Table 4).

Table 5 shows the relationship between L_{50} and L_{\max} as the ratio and its standard deviation, summarized in various ways, including by sample, area, years within areas, and groups of years within areas. The ratios L_{50}/L_{\max} from this study and those summarized by area over a number of years for Icelandic shrimp stocks (Charnov & Skúladóttir 2000) are remarkably similar and not significantly different from each other, in agreement with the observation that this ratio is a biological "invariant" (Charnov 1993, Charnov & Skúladóttir 2000). However, this also holds for the ratio of L_m/L_{50} and L_m/L_{\max} for the same data groupings in Table 5.

DISCUSSION

Stage Structure and Growth Determinations

The results indicate that stage structure (i.e., the combination of the shape of the line joining the chronologically-arranged mean

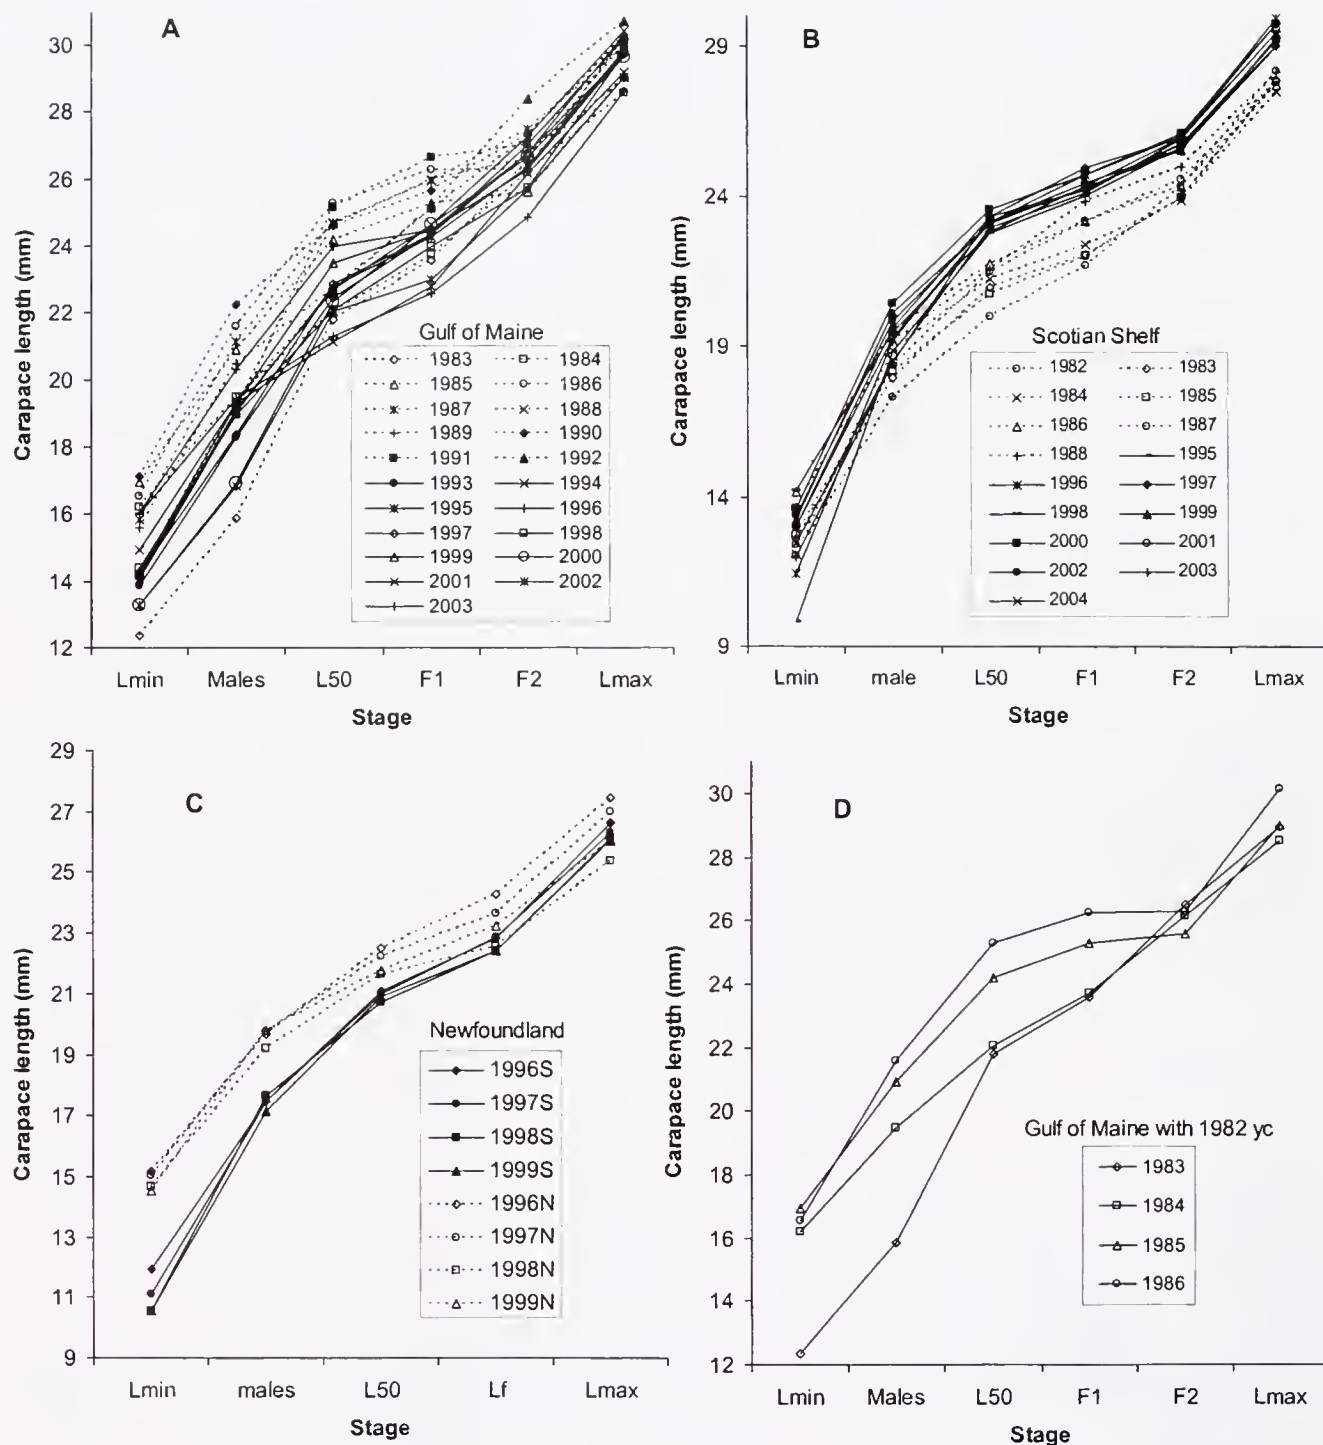

Figure 5. Stage structures for individual survey years in the Gulf of Maine (A), Scotian Shelf (B), northern (N) and southern (S) Newfoundland-Labrador Shelf (C) and the Gulf of Maine survey for 4 y during which a strong year class (1982) was present (D).

stage lengths), and the stage lengths themselves, can provide more information about the growth characteristics of *P. borealis* than the mean lengths of individual stages taken in isolation. For example, both simulations and survey samples showed a straighter stage structure for populations with shorter, and greater curvature for populations with longer, longevity. If longevity does not change over time, as indicated by unchanged curvatures, then an increase or decrease in the lengths of all stages can be taken as an increase

and decrease in growth rate, respectively. Two time periods on the Scotian Shelf previously shown to have different longevity (Koeller et al. 2003) had distinctly different stage structures, including a greater curvature for the period known to have longer longevity. This period also had longer stage lengths, suggesting that the longer longevity was not associated with growth rates low enough to compensate for the associated increase in stage sizes, as seen when comparing Scotian Shelf and Gulf of Maine stage struc-

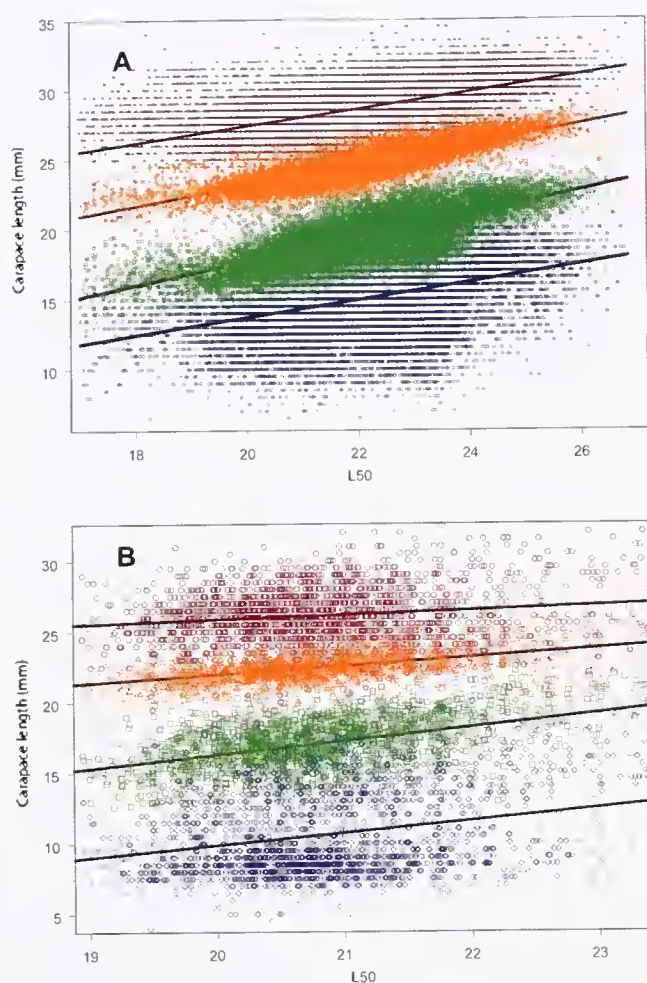

Figure 6. Individual sample estimates of L_{50} plotted against L_{min} , L_m , L_t and L_{max} in the same sample for (A) all commercial samples and (B) survey samples with >200 shrimp.

tures. The differences in stage structures between areas were remarkably consistent over time and reflected the known differences in growth characteristics between areas. The Gulf of Maine stock has the shortest longevity of those examined and the straightest stage structure. It also has the fastest growth rate, which is reflected by its stage sizes that are the same or larger than the slower growing shrimp on the Scotian Shelf and Newfoundland Shelf. The faster growth rate compensates for the smaller stage sizes expected from shorter male longevity alone. The slower growth rate but similar longevity of the Newfoundland Shelf relative to the Scotian Shelf is reflected in its shorter stages and similar stage structure. A greater longevity, such as has been reported for parts of the Newfoundland Shelf (e.g., Parsons et al. 1989) in combination with slower growth would have resulted in similar stage lengths but greater curvature of the stage structure.

An Example Application of Stage Structure Analysis

Koeller et al. (2006) showed that the carapace lengths of most shrimp stages decreased on the entire Newfoundland shelf during the 1990s, with the greatest decrease occurring from 1996–1999 in the northern part of the shelf (Fig. 5C). In addition, shrimp on the northern shelf are generally larger than those in the south. Figure 5C shows that before the large decline in stage sizes (1996–1997)

Figure 7. Stage structure for commercial and survey samples at the median and the 1st and 3rd quartile boundaries of L_{50} . The number of samples used to calculate medians and means around the quartiles are ~1,000 for commercial and ~200 for survey samples. Standard deviations are shown only for the median.

the shape of the stage curves on the northern area are straighter and all stage sizes larger than on the southern Newfoundland Shelf, suggesting that shrimp in the north have both a shorter longevity and faster growth. This is also supported by the larger L_{min} s in the north—shrimp are much larger before they begin to enter survey nets here, suggesting that they grow very quickly during their first year. The greater curvatures in the north during 1998–1999 may then be because of an increased longevity, but with a concurrent decrease in growth rates because the stages are not larger. These slower growth rates could have resulted from decreased primary

TABLE 3.

production during the late 1990s by the mechanism suggest by Fuentes-Yaco et al. (2006). They hypothesized that the shrimp stages on the northern Newfoundland Shelf are much larger because of faster growth rates from the enhanced primary production at and near the mouth of Hudson Strait (Sutcliffe et al. 1983, Drinkwater & Harding 2001), and that the greater size decrease in this area was because of slower growth from a greater decrease in this enhanced production. The latter could have occurred if the greater amount of freshwater runoff received by the northern Newfoundland Shelf through Hudson Strait during the warming trend of the late 1990s increased water column stratification and decreased nutrient influx into the euphotic zone. This theory is in contrast to the generally accepted explanation of why shrimp in more northern areas are usually larger: that they grow more slowly in colder northern waters, but are larger because they live longer. Limited sampling in the northern areas did not allow satisfactory modal analysis to determine growth rates and longevities more directly. Note that results from the Gulf of Maine also contradict the general observation that faster growth and shorter life spans lead to smaller maximum sizes. L_{\max} , and other stage lengths in this area, appear to be at least as large as in the slower growing northern stocks.

Stage Structure and Theories of Sex Change

Stage structure analysis may provide insight into existing theoretical treatments of protandry (Charnov 1982, Charnov 1993, Charnov & Skúladóttir 2000) and the sometimes-conflicting observational evidence supporting them (Bergström 1997, Koeller et

al. 2000, Koeller et al. 2003, Cipriani & Collin 2005, Gardner et al. 2005, de Jong 2005, Nee et al. 2005). The most controversial theory derived from field observations of sex change in *P. borealis* involves the apparent invariance of the ratio L_{50}/L_{\max} off Iceland, which Charnov & Skúladóttir (2000) use to surmise fundamental, mathematically-expressed (in terms of common growth and mortality parameters) rules defining the size at which animals change sex. Nee et al. (2005), de Jong (2005) and Cipriani and Collin (2005) demonstrated that the test for invariance (i.e., a slope of 1 for regressions of log-transformed variable pairs suspected of being invariant) is also positive when bounded variables are generated randomly. However, Cipriani and Collin (2005) also showed that the results of Charnov and Skúladóttir (2000), when expressed as ratios of L_{50}/L_{\max} rather than regression statistics, support the hypothesis that the Icelandic results arose from life-history invariant-related, and not random, processes. The present results suggest that the ratio L_{50}/L_{\max} is indeed invariant for other *P. borealis* stocks and not statistically different from the Icelandic results. However, they also indicate that its status as an invariant is not unique—similarly insignificantly different mean ratios and low standard deviations were obtained for other ratios, including ones without L_{50} as one of the parameters e.g., L_m/L_{\max} . Clearly, although the invariance of L_{50}/L_{\max} does not appear to be an “illusion” as suggested by Nee et al. (2005), the contention that it constitutes a fundamental principle in the evolution of sex changing animals should be examined in light of the present results.

Within-sample relationships between L_{50} and the other stages, including the apparent invariance between stages, manifest themselves statistically only when the average stage lengths of many samples are regressed against each other (Fig. 6A), or when within-sample average stage lengths are averaged over many samples (Table 5). Whereas the relationships between stages are relatively constant or invariant “on average” there is still a large amount of residual variation as shown by the wide scatter around the regression lines in Figure 6. Given that the within-sample relationships between stages are mainly determined by growth processes, which in turn are driven by local food availability and temperature, the “cigar-shaped” edges of the scattergrams in Figure 6 must represent the physiological limits of length and growth for all stages. This is supported by the decreasing scatter at either end of the “cigars.” More constraints and less variation are to be expected near these limits, a situation analogous to the decrease in variation of winning statistics at extreme levels of sports achievements, which are near the physiological limits of the species concerned. Under these circumstances it is not surprising that the

TABLE 5.

Ratios of various stage pairs summarised by sample, area and year, including L_{50}/L_{\max} , the ratio considered to be a biological “invariant” (Charnov & Skúladóttir 2000). There is no significant difference between the means within any set of ratios. All samples were collected from scientific surveys except for Newfoundland commercial samples.

	L_m/L_{\max}		L_m/L_{50}		L_{50}/L_{\max}		Level of data aggregation	N
	Mean	SD	Mean	SD	Mean	SD		
NFLD commercial	0.68	0.05	0.88	0.05	0.77	0.04	Sample	19705
NFLD survey	0.65	0.06	0.82	0.08	0.80	0.07	Sample	2158
Iceland (Charnov and Skúladóttir 2000)	—	—	—	—	0.80	0.01	Area	21
Scotian Shelf (1982–88)	0.66	0.03	0.87	0.02	0.76	0.03	Year	7
Scotian Shelf (1995–2004)	0.66	0.02	0.84	0.03	0.79	0.01	Year	10
Gulf of Maine	0.65	0.05	0.84	0.05	0.78	0.04	Year	21

ratios of stage lengths are, on the average, invariant. The regression lines in Figure 6 and ratios in Table 5 represent average stage lengths and growth rates over a wide range, bounded by the "cigar" shapes. Provided that there are enough samples to represent this average adequately, it should always converge to the same number.

These results suggest that it is the variance in growth rates and size of life history stages, not the invariance in the ratios between stages, which is most remarkable and informative about the biology of *P. borealis*. Although the ultimate mechanisms behind the evolution of a protandric life history strategy is beyond the scope of this paper, the present results suggest that this plasticity in growth rates and sizes of life history stages should be an important consideration in theoretical treatments, at least for *P. borealis*.

A Conceptual Growth Model for *P. borealis*

The two most remarkable and informative aspects of the stage structure of *P. borealis* are the observations that stage lengths are strongly related to each other within samples and that environmental, temporal and spatial factors influence the lengths of all stages. If the relationship between L_{50} and L_{max} (i.e., the apparent invariance of the ratio L_{50}/L_{max}) results largely from growth process as suggested by Charnov and Skúladóttir (2000), Koeller et al. (2003) and this paper, one would expect this relationship to manifest itself only after the application of appropriate time lags to summarized data averaged by area and year. The achievement of maximum size in *P. borealis* follows sex change by at least two years, because there are at least two, and probably more, female age classes. Why is a relationship between life history stages separated in time, purportedly because of growth, so evident in individual samples where spatial, not temporal relationships should be most prominent? One obvious answer is that the observed within-sample relationships between stages do not result from growth but rather from schooling or migratory behavior that brings similar sizes together at the same locations. Ontogenetic migrations into deeper water have been inferred from the common observation that shrimp sizes (including average stage sizes) often increase with depth (reviewed in Shumway et al. 1985). Because larger shrimp are expected to migrate faster this mechanism would tend to segregate size groups along depth gradients. Another possible mechanism is vertical migration and associated horizontal displacement. Different sizes of shrimp tend to have different vertical migration ranges (Shumway et al. 1985), consequently a size group migrating vertically into layers with faster horizontal current speeds will be displaced farther than other groups. Over time this would have a "winnowing" effect, bringing shrimp of similar size to the same areas. However, this does not explain the temporal changes observed within areas, where length differences between years, or groups of years, tend to affect all stages (e.g., Scotian Shelf, Fig. 3B). In addition, it seems unlikely that such migrations or displacements, which must be quite variable between areas and times, would result in such invariant relationships between stages.

Assuming that the observed within-sample relationships between stages result from growth processes, these relationships could have come about only if growth rates of all stages (and ages) were highly sensitive and responsive to changes in local conditions, especially food availability and temperature. Shrimp of all sizes consume phytoplankton, detritus (i.e., senescent phytoplankton blooms), or small herbivorous zooplankton, therefore growth of all stages is strongly influenced by a common factor—food availability, as determined by primary production and shrimp den-

sity (Koeller et al. 2006, Fuentes-Yaco et al. 2006). In addition, shrimp of all stages at any location and time are subject to the same temperatures, arguably the second most-important modifier of growth rates (after food availability) in poikilotherms. Consequently, the growth rate of shrimp of all sizes, stages and ages present at any location will respond simultaneously to changes in the physico-biological conditions in the area, especially food availability and temperature. Moreover, in a situation where P/B ratios and natural mortality are high (M of 0.75 has been used in stock assessments), temporal changes in growth should become evident through a simultaneous change in all mean stage sizes almost immediately (i.e., in the same year). Significant correlations between environmental variables and the size (growth) of the later life history stages are therefore expected without time lags, as found by Fuentes-Yaco et al. (2006).

The strong positive relationship between depth and all shrimp stages off Newfoundland supports the conclusion that the within-sample relationship between stages is caused by growth processes. In this area depth is strongly (positively) related to temperature and can be used as a proxy for temperature, albeit without temporal components. In addition, the abundance of the high organic content sediments and particulate organic carbon deposition, which form an important food source for shrimp, tends to increase with depth (Ramseier et al. 2000). Because temperature and food availability increase with depth, growth rates are expected to do the same. Similar site (depth) specific growth rates caused by differences in local conditions have been observed for scallops in the Bay of Fundy (Smith et al. 2001). For shrimp, the strong relationship between environmental, temporal and spatial factors other than depth and all shrimp stages is further support for the conclusion that the within-sample relationship between stages arises because these factors influence the growth rate of all stages simultaneously and are highly site-specific.

The growth rate of *P. borealis*, a poikilotherm, is strongly influenced by temperature and food availability, both of which vary widely spatially and temporally in its huge geographic range (~2400 nautical miles between latitudes 40°N and 80°N). Consequently, growth rates must vary widely, spatially and temporally. Most eggs are produced by only 2-yr classes (F1 and F2 females). If sex change were triggered by size alone, a decrease in growth rate caused by changes in environmental conditions could delay sex change by a year or more before this size would be achieved, leading to a large decrease in egg production during the delay period if other factors affecting egg production, such as population size and spawning frequency, remain constant. Changing sex after a fixed number of years ensures a stable annual egg production. However, because the number of eggs a female produces is directly related to its size (Schumway et al. 1985), changing sex at a fixed age will result in significant decreases in egg production if growth rates are very slow. Consequently, the highly variable growth rates caused by environmental influences forces a compromise between stability and quantity in egg production. How might a sex changer manage this balance and become as successful in terms of abundance and geographical range as *P. borealis*? Because a fixed age or size at sex change coupled with highly variable growth rates can carry major penalties for fecundity, the answer must lie in flexibility. This flexibility is achieved if the size at sex change is fundamentally (i.e., physiologically) linked to growth and metabolic rates, which in turn are linked to environmental changes in temperature and food availability. This appears to be the case for *P. borealis* (Koeller et al. 2003, Charnov and

Skúladóttir 2000). Given that stage structures result from growth processes, the strong relationship between all stages (including size at sex change) shown in this study further support this theory. Formally and simply stated, sex change occurs earlier in time when growth rates are faster and later in time when they are slower.

Because environmental conditions tend to be relatively stable within limited geographical boundaries (e.g., within SFAs or stocks), growth rates, stage lengths and size/age at sex change vary less within subareas and stocks than between them. Under stable environmental conditions within-stock growth rates are similar and sex change occurs at the same year and size. However, the number of male year classes does change occasionally within stocks, either between environmental regimes (Fig. 5B, Koeller et al. 2003), or when only part of a large year class changes sex, a situation which is known to occur with large year classes, which tend to have slower growth because of density-dependant factors (Koeller et al. 2005, M. Aschaan, pers. comm. U. Skúladóttir, pers. comm.). If growth rates decrease greatly because of decreasing temperatures and food availability, sex change will come later in time. However, sex change is constrained to a short "window of opportunity" within the annual physiological/reproductive cycle, consequently if slower growth rates delay sex change in time this window may be missed and sex change delayed by a year. The opposite occurs if growth rates increase because of increasing temperatures and food availability. In this model the year and size at sex change are not magic numbers but simply the age and size a shrimp happens to be at the time sex change occurs, as dictated by growth/metabolic rates, and the yearly life cycle. Similarly, the relationship between the size at sex change and the maximum size achieved (i.e., L_{50}/L_{max}) are "invariant" only because growth rates are largely environmentally driven and affect the sizes of all stages including males, transitionals, females and L_{max} .

Limitations and Potential of Stage Structure Analysis

As used above, stage structure analysis allows for only qualitative, or semiquantitative observations on the relative differences in growth characteristics between areas and time periods (e.g., growth rates are slower or faster, longevity is longer or shorter). More sophisticated modeling approaches, such as tuning model results to observed stage structures, may provide more quantitative results, however, the present approach can still be useful in comparative studies, e.g. the Newfoundland-Labrador shelf problem described above.

The application of the model used in this study to infer growth characteristics of other invertebrates is limited. Modeled longevity is solely caused by differences in the number of male year classes, the number of female year classes is constant at 2, and the mortality of females older than 2 y is total. Although not completely correct in detail, this appears to capture the main aspects of *P. borealis* life history, as evidenced by the similarity of simulations and field observations. However, it is specific to protandic hermaphrodites such as *Pandalid* shrimp. Still, the general approach of comparing or tuning model life history stage and age structures with known growth characteristics may be applicable to non-sex changing invertebrate species with distinct life history traits that are fairly short in duration.

Stage structure must also be influenced by factors other than growth, which may limit its usefulness for making inferences on growth in certain situations. This is illustrated by the large differ-

ences in stage structure between commercial and survey samples (Fig. 7). Because they cover the same stock (Newfoundland-Labrador), these differences may be because of factors other than growth, in particular sampling time (throughout the year for commercial, late fall for survey), sampling strategies (seeking concentrations of large shrimp for commercial versus randomly distributed throughout its range for surveys) and fishing gear (square mesh cod-ends and Nordmøre selectivity grids for commercial, small mesh cod-end liners for survey). Despite these different methodologies much of the difference in stage structure in Figure 7 can still be attributed to differences in growth, specifically to different growth rates in the locations sampled by these two methods. Commercial fishing operations concentrate in deep water where larger shrimp of all stages are found, presumably caused by faster growth, consequently all stages are larger and the stage structure is straighter for commercial data. Nevertheless, some of the differences in lengths, especially for smaller stages like L_{min} , are probably caused by differences in cod-end mesh sizes. The site-specific nature of stage lengths/growth rates and the large differences between locations within years implies that within-year spatial variability must be accounted for when making between-year comparisons, especially for survey samples. Another important modifier of stage structure other than growth is the passage of large year classes through the population. Shrimp recruitment is strongly influenced by environmental factors (Koeller 2000) and this tends to be exacerbated in highly exploited populations, like the Gulf of Maine stock. However, the passage of year classes through the stage structure is sequential, and should be distinguishable from a change in growth rate, which tends to be simultaneous. Comparisons between survey series may be complicated by large differences in survey times, for example, comparisons between the spring-summer surveys in the Gulf of Maine and Scotian Shelf versus the fall-winter Newfoundland-Labrador surveys must take into account growth and other processes between survey times that may have influenced stage structure. More work is required to clarify the effect of various processes on population stage structure, including, but not necessarily restricted to, gear selectivity, mortality and recruitment i.e., the influence of strong year classes and associated density-dependant effects on growth rate.

Changes in the abundance of *Pandalid* species have been used as indicators of ecosystem regime shift in the North Pacific (Anderson 2000) and the North Atlantic (Koeller 2000, Lilly et al. 2000). In both oceans changes in *Pandalid* abundance are associated with both climatological change and predator abundance. Shrimp are uniquely situated trophically and are potential indicators of changes in both "top down" and "bottom up" processes throughout the marine ecosystem. In terms of the latter, their growth is affected by primary production processes, because they consume phytoplankton and small herbivorous zooplankton (Fuentes-Yaco et al. 2006). Climatological changes that affect water temperatures will also affect shrimp growth. A change in the growth rate of a shrimp stock as determined by a simultaneous increase or decrease in the carapace lengths of all stages may be an early indicator of fundamental environmental and ecological changes that will eventually affect other ecosystem components. The results in this paper suggest that the great plasticity of shrimp growth rates in response to environmental changes is a property that can also be used to practical advantage in fisheries and ecosystem management (i.e., as an early indicator of ecological change in the lower trophic levels).

CONCLUSIONS

1. Stage structure analysis is useful in spatial and temporal comparisons of growth rates for *P. borealis*. It is more informative about growth rates than an examination of single stages, such as the size at sex transition, L_{50} , or the maximum size, L_{max} , in isolation.
2. When longevities do not change, as evidenced by a constant shape of the stage structure in time, a simultaneous increase in the mean length of all stages is indicative of an increase in growth rates, and vice versa.
3. The passage of a strong year class through the population can have a significant effect on stage structure, however it is a sequential event, distinguishable from a change in growth rate, which tends to affect mean size of all stages simultaneously.
4. Growth rates of *P. borealis* are highly site-specific and sensitive to environmental influences, particularly temporal and spatial changes in food availability and temperature.
5. The time of sex change is directly related to growth and metabolic rates (i.e., sex change comes later when growth rates are slow and earlier when growth rates are faster). Consequently, the age and length at sex change is highly flexible, and only constrained by the timing of the annual

reproductive cycle. This avoids the negative impacts of a fixed age or length at sex change on egg production in a species whose growth rates are dependent on highly variable environmental factors, and whose fecundity is strongly related to size.

6. The "invariant" relationship between L_{50} and L_{max} is not unique to these stages and simply a consequence of the strong relationship between environmental factors and growth rates of all stages.
7. The stage structures of *P. borealis* populations could be early indicators of fundamental environmental and ecological changes in the ecosystem.

ACKNOWLEDGMENTS

The author thanks Joseph Idoine for making the Gulf of Maine survey data available, and David Orr for providing the Newfoundland-Labrador survey and commercial data. César Fuentes-Yaco, Trevor Platt, Sandra Shumway, Kai Wieland and one anonymous reviewer provided helpful comments, suggestions and discussion on an earlier draft that substantially improved the manuscript. Stephen Smith provided technical assistance with S-PLUS and statistical advice.

EFFECTS OF TIDAL RESTRICTIONS AND POTENTIAL BENEFITS OF TIDAL RESTORATION ON FECAL COLIFORM AND SHELLFISH-WATER QUALITY

JOHN W. PORTNOY*¹ AND JENNY R. ALLEN²

¹Cape Cod National Seashore, 99 Marconi Site Road, Wellfleet, Massachusetts 02667; ²University of Massachusetts, Wildlife and Fisheries Conservation, Holdsworth Hall, Amherst, Massachusetts 01003

ABSTRACT The relationship between artificial tidal restrictions and shellfish-water quality was studied within otherwise sparsely developed estuaries on Cape Cod (Massachusetts, USA). The primary study site, the 600-ha diked Herring River (Wellfleet, MA) estuary, has had a long history of shellfish-water closures because of water-column fecal-coliform (FC) contamination despite the lack of human fecal sources. Ongoing efforts to restore tidal flow to the system have raised questions about the effects on microbiological water-quality on extensive beds of wild oysters (*Crassostrea virginica*) and cultured hard clams (*Mercenaria mercenaria*) in the river mouth. This study combines observations of current spatial and temporal (tidal) patterns of water-column contamination with recent hydrodynamic modeling to predict the effects of proposed tidal restoration on shellfish-water quality. Under presently tide-restricted conditions, high FC is restricted to about 1000 m on either side of the dike structure and only during low tide, preventing the harvest of extensive natural oyster beds; farther downstream, hard-clam aquaculture is marginally protected by relatively coliform-free, high-salinity Cape Cod Bay waters. Modeling of Herring River under tide-restored conditions showed that a predicted 13-fold increase in river intertidal volume, over existing tide-restricted conditions, would dilute measured FC to concentrations that are acceptable for shellfish-growing waters. Restored tidal flow would also reduce coliform survival time by increasing salinity, dissolved oxygen and pH, all presently depressed throughout the system because of the biogeochemical disturbance of diking and drainage. Results from Herring River, plus a preliminary survey of other diked Cape Cod estuaries, suggest a direct relationship between the degree of tidal restriction and surface-water FC, which should be studied further.

KEY WORDS: fecal coliform, diking, salt-marsh restoration, aquaculture

INTRODUCTION

Efforts to restore native habitats in historically tide-restricted salt-marsh estuaries primarily focus on removing artificial barriers to tidal exchange. In the context of past diking, filling and drainage, it is generally agreed that re-establishment of the original hydrology, hydrography, and salinity distribution is fundamental to restoring an estuarine ecosystem (Niering & Warren 1980, Burdick et al. 1997, Roman et al. 1995). Although this is an ecologically reasonable approach for restoring dominant estuarine processes and biota, actual restoration management must also consider human-land-use changes that can affect the nature, and social acceptability, of system response.

A most obvious recent land-use change along the US coast is the rapid increase in human population and development. One outcome of the development increase has been an apparent decline in microbiological water quality, typically monitored using coliform indicator bacteria. In particular, fecal coliform (FC) contamination has forced the closure of shellfish beds throughout the US coasts. Although this pollution is usually attributed specifically to an increase in development-related sources (e.g., agriculture, impermeable-surface runoff and wastewater, Mallin et al. 2001), coastal development has also likely affected bacterial transport and dilution, through altered coastal hydrography including tide restrictions.

Tides were first restricted in New England coastal wetlands, predominantly for road and railway construction and mosquito control, in the late 19th and early 20th centuries. Tide restrictions reduce the tidal prism and thereby limit seawater flushing and dilution of constituents delivered to the estuary in discharging freshwater; this dilution is reduced both landward and seaward of the restricting structure. In this purely physical way, tide restrictions may effectively increase fecal coliform concentrations in

coastal waters. Increasing development, road runoff and bacterial loading would have exacerbated the problem.

In addition, disturbance to salt marsh biogeochemical cycling and resulting water-quality degradation caused by diking could contribute to FC survival and management problems in diked wetlands. The blockage of tides reduces salinity; tide-restricted marshes are poorly flushed, leading to high oxygen demand and low summertime dissolved oxygen (Portnoy 1991); and drainage causes acid sulfate soil formation and low water-column pH (Gosling & Baker 1980, Sammut et al. 1995, Portnoy 1999). Low salinity increases coliform survival times in the environment (Carlucci & Pramer 1960, Goyal et al. 1977, Morinigo et al. 1990, Coelho et al. 1999, Lipp et al. 2001, Gabutti et al. 2000, Mallin et al. 2000, Bordalo et al. 2002).

Conversely, tidal restoration would reduce fecal bacteria concentrations, regardless of their source, first through simple dilution because of a much-increased tidal prism. In addition, increased salinity would reduce the survival time of enteric bacteria in the environment, as studies elsewhere have consistently demonstrated (Mallin et al. 1999, Coelho et al. 1999, Gabutti et al. 2000, Mallin et al. 2000, Lipp et al. 2001). Finally, laboratory and field experiments have shown that tidal restoration can quickly restore water-column pH (Portnoy & Giblin 1997a, Easton & Marshall 2000), further depressing coliform survival.

Chronically high fecal coliform and shellfish-waters closures just seaward of a large Cape Cod estuary planned for tidal restoration prompted this study. Extensive beds of eastern oyster (*Crassostrea virginica*, Gmelin 1791) up to 2 km seaward of the diked 600-ha Herring River estuary (Wellfleet, MA, USA) have been closed, at least seasonally, because of fecal coliform contamination since state-wide surveillance increased about 1983. With the largest hard clam (*Mercenaria mercenaria*, Linnaeus 1758) aquaculture beds in Massachusetts just seaward of the zone of chronic closures, there was public concern that tidal restoration could extend the FC problem to close a highly productive fishery. Coastal

wetlands can be important sources of public-health indicator bacteria, reportedly because of the abundance of organic matter, nutrients and high water-column turbidity promoting bacteria survival (Jenson et al. 1980). Enterococci produced in a California tidal marsh affected surf-zone water quality under specific near-shore flow conditions (Grant et al. 2001).

The Herring River estuary is largely undeveloped, with very few cesspools or septic systems near the river and few road crossings, because of incorporation of 80% of the floodplain into Cape Cod National Seashore in 1961. Therefore, we began the study with the assumption that wildlife within the river basin was probably the major ultimate source of FC in surface water. Waterfowl and other birds can be abundant in or near the river and are probably a major ultimate source of coliform bacteria; these microbes can reportedly survive and perhaps grow in sediment (Gerba & McLeod 1976, Struck 1988). If this is the case for Herring River, bacteria could be resuspended with surficial sediment during periods of high freshwater discharge and/or tidal flow, to constitute an important proximate source to the receiving water column (Mallin et al. 1999, Grant et al. 2001). Because this source has not, given land-use history, recently changed, nor is it likely to substantially change with tidal restoration, we focused instead on the water quality and hydrodynamic factors that would affect coliform survival and transport under both existing and tide-restored conditions. The general goal was to use existing conditions together with recent hydrodynamic modeling results (Spaulding & Grilli 2001, 2005) to predict the effects of tide restoration on bacteria concentrations in downstream shellfish-growing waters.

Specific objectives were: (1) to describe where and when public-health bacteria contaminate presently restricted estuarine surface waters and (2) to predict how restored tidal exchange would affect shellfish-water quality.

STUDY AREA

Herring River

The 600-ha Herring River estuarine complex (42°N, 70°W), occupying a glacial outwash valley on the eastern shore of Cape Cod Bay (Fig. 1), is the largest diked wetland system on Cape Cod (Portnoy 1991). Tidal flow to most of the original salt marsh was eliminated by inlet closures in the eighteenth and nineteenth centuries, and by a dike built across the mouth of the main stream in 1909. Stream channelization and ditch drainage began before dike construction but intensified immediately thereafter; channel and ditch maintenance continued until 1984. The modern dike structure includes three 4-m² rectangular sluiceways providing a large opening for freshwater discharge (ranging 0.2–0.5 m³ s⁻¹) at low tide. During high tide, hydraulic pressure closes top-hinged doors (clapper valves) on two of the sluiceways, preventing seawater flow upstream. The third sluiceway is partially open (cross-sectional area about 1 m²) allowing some seawater entry; however, seawater flow up the main channel and onto the diked marsh surface is limited to 1,000 m upstream. The dike reduces tidal range from about 2.1 m seaward, to 0.5 m landward of the structure. At high tide in the river, saltwater extends only to Station 3; at low tide, salinity at the dike is about 15 ppt, decreasing to 0–3 ppt at Station 4 (Fig. 1). Because of the previously mentioned lack of tidal flushing and biogeochemical disturbance, the river above the reach of seawater suffers from low pH and low dissolved oxygen (Soukup & Portnoy 1986, Portnoy 1991). Approximately 15 ha of natural

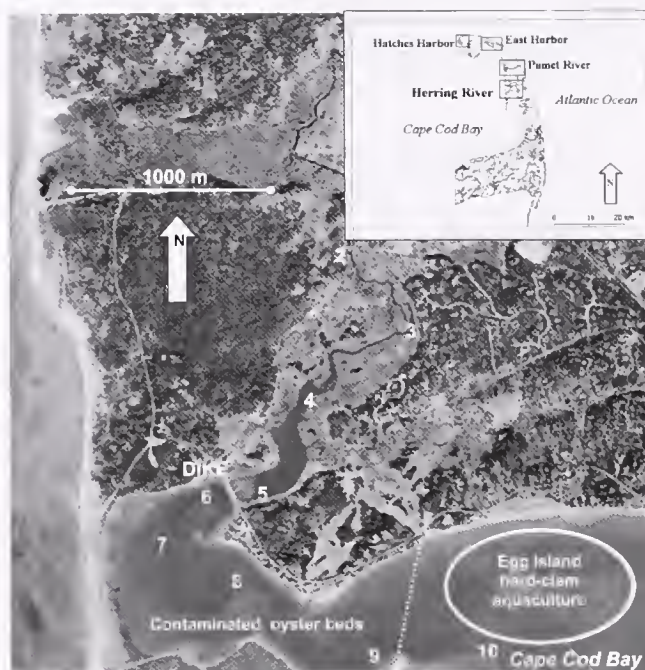

Figure 1. Herring River study area, water-quality sampling stations and location of hard-clam aquaculture and oyster beds. Inset: location of Herring River and other study sites on outer Cape Cod.

oyster beds and 20 ha of hard-clam aquaculture (Egg Island) at the river mouth, and seaward of the dike, are indicated on Figure 1.

Historic photographs taken just before the 1908 diking show an apparently continuous stand of salt marsh grasses along the shore of the Herring River. Core analyses by R. A. Orson (Roman 1987) documented the presence of smooth cord grass (*S. alterniflora*, Loisel) on the floodplain presently vegetated with velvet grass (*Holcus lanatus*, Linnaeus), meadowsweet (*Spiraea latifolia*, Ahles) and hardhack (*S. tomentosa*, Linnaeus) goldenrod (*Solidago* spp.) and black cherry (*Prunus serotina*, Ehrhart). Because of peat drainage, pore-space collapse and accelerated decomposition (Portnoy & Giblin 1997b), the marsh surface elevation is 0.95–1.01 m NGVD (National Geodetic Vertical Datum), or about 90 cm below modern unaltered *Spartina* marsh seaward of the Herring River dike.

Regarding sources of FC, impermeable surfaces comprise only two paved secondary roads crossing the floodplain, and there is only one domestic wastewater disposal system within 20 m of surface waters. Waterbirds, primarily waterfowl (Anseriformes), are seasonally abundant and probably a principal source of coliform in the river system (Valiela et al. 1991).

Other Sites

The relationship between the degree of tidal restriction and low-tide FC concentrations was studied at several other Cape Cod estuaries in summer 2005. Pamet River (Truro, MA) has been completely tide restricted since about 1867, with no seawater passing through a dike that cuts off all tidal flow from the upper 64 ha of this wetland. The diked wetland is vegetated with freshwater-wetland shrubs, narrow-leaved cat-tail *Typha angustifolia* (Linnaeus) and common reed (*Phragmites australis*, Trinius).

East Harbor (Truro, MA) is a 145-ha back-barrier lagoon and 150-ha emergent wetland, also isolated by diking from the marine

environment since about 1868. Salinities have increased greatly in the East Harbor lagoon since 2002, from 4–20 ppt, when clapper valves in its drainage culvert were opened to improve flushing; however, tidal range remains <0.5 m in creeks immediately above the culvert, and 0 in the lagoon proper because of the small diameter of the culvert relative to lagoon volume. The East Harbor emergent marsh is vegetated with freshwater shrubs, *Typha angustifolia* and *Phragmites australis*.

Hatches Harbor (Provincetown, MA) is a 170-ha back-barrier salt marsh bisected by a dike in 1930; large culverts were installed in this dike and gradually opened beginning in 1999 so that to date (2005) nearly all restriction on tide height and salinity distribution has been removed. As a result of increased salinity, salt marsh herbs are replacing an extensive stand of *Phragmites*.

Like Herring River, these other coastal floodplains are within Cape Cod National Seashore, are consequently sparsely developed and have few sources of anthropogenic coliform pollution.

METHODS

At Herring River, water and sediment sampling focused on nine sites spaced roughly 0.5–1.0 km apart along the main stem from above the reach of seawater (Station 2) to the mouth of the river at Egg Island (Station 10), a sandbar in Wellfleet Harbor used intensively for bivalve aquaculture (Fig. 1). Other estuaries were sampled within 50 m above and below road crossings that restricted tidal flow. Most sampling effort was directed toward FC bacteria because this group is the water-quality standard for shellfish-growing waters per the US Food and Drug Administration's National Shellfish Sanitation Program. Field-work, including periodic surface-water sampling and sediment collections, was conducted from May through October of 2005. Following preliminary surveys of FC throughout the tidal cycle, sampling focused on low tide to characterize worst-case conditions.

Sediment

Sediment was collected by Ponar dredge on two dates at water-quality stations in Herring River. Dredged sediment was dropped upright into a basin and the top 2 cm transferred to a sterile cup using a flame-sterilized spoon. To control for expectedly high spatial variability, three randomly located grabs were collected at each sampling station and combined together in equal volumes.

In the laboratory, these composited samples were thoroughly mixed to homogenize. 20 g of wet sediment were removed aseptically, mixed with 200 mL of phosphate buffer, shaken for 45 min, and allowed to stand for 30 min. *E. coli* MPN (most probable number) in 100 mL of the supernate was determined using the Colilert-18 system (IDEXX Laboratories, Westbrook, Maine); incubation temperature was 35°C. Remaining sediment was dried at 105°C, dry-sieved for particle size distribution and combusted at 550°C, for 2 h to determine organic content. Bacteria concentrations were computed per unit of dry sediment weight.

Water

Surface-water samples were collected aseptically at about 10-cm depth, transported to the laboratory at 4°C and cultured for FC using the membrane filtration method at 44.5°C on M-FC agar with rosolic acid (APHA 1998) within six hours of collection. All water samples were collected and cultured for FC in duplicate; data are presented as means \pm 1 SD. On two dates (August 4 and 11, 2000), samples from all Herring River stations, plus Hatches

Harbor, East Harbor and Pamet River study sites were also tested for *E. coli* using the Colilert-18 system; as for sediment (above) incubation temperature was 35°C; results are presented as MPN (most probable number) per 100 mL. The Colilert system has been shown to perform as well or better than traditional membrane-filtration methodology for these bacterial indicators (Yakub et al. 2002).

Note that for Herring River sediment, *E. coli* was cultured, as opposed to FC in water samples; this was simply because an FC method was not available for sediment using the IDEXX system. We therefore do not directly compare densities of FC in water and *E. coli* in sediment, but rather compare their respective spatial patterns along the estuarine salinity gradient. *E. coli* is of course a major component of fecal coliform.

Salinity was measured by refractometer. Turbidity was measured with a Hach 2100P turbidimeter, calibrated with primary formazin standards.

RESULTS

Sediment

Highest *E. coli* concentrations were found in sediment at stations 200–1,400 m above the dike (Fig. 2). Because of the tide restriction, this is a reach of limited tidal range and flood-tide velocity; therefore, fine particles tend to deposit directly into the channel. In comparison, concentrations above this river reach were relatively low on both sampling dates. Immediately seaward of the dike, sediment bacteria were moderately high in July but low in August. From about 500 m of the dike structure to the channel south of Egg Island, *E. coli* was low to undetectable on both sampling dates. Bacteria density was related to sediment physical properties as measured at these sampling locations (Table 1): *E. coli* appeared highest in relatively fine-grained sediments with low bulk density and high water content.

Surface Water

A preliminary survey in May 2005 of surface-water FC at 30 min intervals from midebb to midflood tide just seaward of the dike structure (Station 6, Fig. 1), showed that highest concentrations occurred at lowest salinities coinciding with low tide in the diked river (Fig. 3). In addition, a survey of all nine river stations at both low and high tides on the same date in October (Fig. 4) showed a similar relationship between tidal stage and FC: essentially, FC varied inversely with salinity at stations 5 through 10 from just above to 2,000 m seaward of the dike; FC at Stations 2–4 in the diked river proper was similar at both high and low tide. Given these observations, to characterize worst-case conditions most other water sampling was conducted at low tide.

Repeated low-tide sampling throughout the summer months corroborated the relationship between FC and position along the river main stem (Fig. 5): FC was low to moderate at Stations 2 and 3, high at Stations 4 through 8, about 1,000 m above and below the dike, respectively and very low at Stations 9 and 10. On September 18, Tropical Storm Ophelia delivered one of only two substantial (>1 cm) rain events during the summer to the study area. During the resulting freshet, low-tide FC increased 2- to 4-fold at Stations 2 through 8, and about 80-fold at Stations 9 and 10; however, the same relationship between FC and river reach was observed as during drier weather, albeit with much higher values, indicative of increased FC discharge from upstream wetlands (Jenson et al.

Figure 2. *E. coli* concentrations (colony forming units per g DW) in Herring River sediment on July 20 (top) and August 16 (bottom) 2005.

1980). Concentrations returned to background dry-weather conditions 5 days after the September 18 rain event.

Although highest low-tide, surface-water concentrations of FC consistently occurred at and just seaward of the river reach with highest sediment stocks of *E. coli* (Fig. 2), FC did not vary with

TABLE 1.

Correlation coefficients (Pearson's *r*) between *E. coli* concentrations and sediment physical properties at Herring River stations in summer 2005; *n* = 22. Significance levels are given in parentheses.

Collection Date	Median Grain Size	Water (%)	Organic Matter (% DW)	Bulk Density (g cc ⁻¹)
20 Jul	-0.638 (0.03)	0.610 (0.05)	0.496 (0.12)	-0.650 (0.03)
16 Aug	-0.514 (0.11)	0.430 (0.18)	0.286 (0.39)	-0.445 (0.17)

turbidity as from suspended sediment ($R^2 = 0.08$, $P < 0.05$). A plot of all turbidity and FC observations versus salinity showed a complex relationship (Fig. 6), with high turbidity at both freshwater and marine end members, and moderate and low FC respectively; lowest turbidity corresponded with highest fecal coliform concentrations at low-tide salinities of 10–25 ppt, typically within 1,000 m above and below the dike.

Physical Effects of Tidal Restoration

Hydrodynamic modeling, conducted to assess physical alternatives for tide restoration (Spaulding & Grilli 2001, 2005), showed that tidal range could increase from 0.5–2.0 m, and intertidal volume from about 73,000–980,000 m³. Assuming most of the water that exited the river during the ebb did not return during subsequent flood tides, as evidenced by consistently high flood-tide salinity, the increase in intertidal volume amounts to a 13.4-fold increase in the dilution of river water. Given this dilution factor, and assuming that bacterial loading does not increase, restored tidal flushing should reduce coliform bacteria to concentrations below the standard for shellfish waters (Fig. 7), except for low-tide periods 2–4 days after heavy rain.

Other Study Sites

Although seasonal use by waterfowl, larids and roosting passerines may be one factor contributing to high FC above the Herring River dike structure (Moles 2005), another appears to be the effect of tide restriction itself on water and sediment quality. This is supported by less intensive sampling in the other large diked salt marshes on Cape Cod. We noted on two sampling dates in mid-summer that low-tide FC and *E. coli* in the water column at Pamet River and both East and Hatches Harbors related directly to the degree of tidal restriction, indicated by depressed low-tide salinity (Fig. 8).

DISCUSSION

Current Hydrographic Conditions

Chronically high surface-water FC occurred in the principal zone of river- and bay-water mixing, where low-tide salinities ranged from 10–25 ppt; this zone extended about 1,000 m on either side of the dike tidal restriction. Sediment in the upstream reaches of this zone (e.g., Stations 3 and 4, Fig. 1) had high *E. coli* and may have been the proximate source. Abundance of *E. coli* in Herring River sediment corresponded with an open-water habitat above the dike that was highly attractive to waterfowl and larids (Portnoy et

Figure 3. FC concentrations (± 1 SD) and salinity in Herring River surface water from midebb to midflood tide, May 26, 2005.

al. 1987) and roosting passerines; it is likely that these animals seed the river sediment with coliform bacteria in their droppings. There is increasing evidence that fecal coliform can survive and even grow in the environment, especially in sediment (Gerba & McLeod 1976, LaLiberte & Grimes 1982, Struck 1988, Davies et al. 1995, Grant et al. 2001). Their survival time in sediment would be extended by low salinity (Mallin et al. 2000, Lipp et al. 2001, Anderson et al. 2005), low pH (Carlucci & Pramer 1960), and high sediment organic content (Gerba & McLeod 1976, Matson et al. 1978, LaLiberte & Grimes 1982)—the very conditions that prevailed in Herring River because of the restriction of tides and ditch drainage (Portnoy 1999).

FC concentrations in river surface water were clearly dependent on tidal stage and the amount of fresh water from the high-FC zone just above the dike relative to the high-salinity, and comparatively low-FC, Cape Cod Bay end member (Fig. 3, 4). Low-tide surveys consistently showed that high FC, exceeding the USDA shellfish-waters standard of 14 CFU (colony-forming units) per 100 mL, was the norm for all river stations; in contrast, dry-weather FC was always low at the most seaward Stations 9 and 10 (Fig. 5), demonstrating the predominance of Cape Cod Bay water in the salt and water budget of Wellfleet Harbor. It should be noted, however, that the protection afforded Wellfleet's Egg Island aquaculture industry by clean Cape Cod Bay water was marginal.

Figure 4. Low- and high-tide salinity and fecal coliform (± 1 SD) in Herring River, October 20, 2005.

Figure 5. Low-tide FC (\pm SD) at Herring River stations throughout the 2005 summer including days one (Sep 18), three (Sep 20) and five (Sep 22) after a 8.9-cm rain event.

with observed violations of the water-quality standard during wet weather (Fig. 5). Meanwhile, under current tide-restricted conditions, the extensive oyster beds in the river mouth between Stations 5 and 9 (Fig. 1) were chronically contaminated and closed to shellfish harvest.

Fecal coliforms are often associated with sediment (Faust et al.

1975, Valiela et al. 1991) and can be released into the water column by sediment disturbance (Rittenberg et al. 1958, Matson et al. 1978, Coelho et al. 1999, Mallin et al. 1999, Mallin et al. 2000). This can be a concern in tide-restoration projects if hydrodynamic changes trigger resuspension of FC-rich sediment into bathing or shellfish waters. However, FC has not always correlated well with

Figure 6. FC and turbidity across the Herring River salinity range, all summertime observations.

Figure 7. Estimated dilution effects on Herring River fecal coliform concentrations, relative to shellfish-waters standard, given model-predicted increase in intertidal volume and flushing with tidal restoration. Also shown are locations of oyster and hard clam beds relative to river sampling stations.

turbidity as a measure of sediment resuspension in studies elsewhere (Goyal et al. 1977, Jenson et al. 1980). Indeed, sediment resuspension did not appear to be an important mechanism affecting microbiological water quality under existing conditions in Herring River. Highest FC observed in the river channel corresponded with the lowest turbidities, and midrange salinities (10–25 ppt);

highest turbidities were at opposite ends of the salinity gradient (Fig. 6). The high turbidity at the river mouth (Stations 6–10) was apparently caused by the flocculation of dissolved organic matter and complexed Fe as salinity and ionic strength increased (Fig. 6), a process that is well described for rivers world-wide (Boyle et al. 1977); it was not the result of sediment resuspension. Thus, as

Figure 8. Typical summer fecal coliform and *E. coli* concentrations (mean \pm SD, $n = 2$) in tide-restricted and restored Cape Cod estuaries at low tide. The degree of anthropogenic tidal restriction is indicated by low-tide salinity, indicated over bars; with no restriction, low-tide salinity would be about 30–32 ppt.

river water mixed with seawater at the river mouth during ebb tide, turbidity rose and FC declined. High FC at mid-salinity Stations 4–8 may have nevertheless been caused by tidal stirring in the river channel (Mallin et al. 1999) that was sufficient to resuspend a bacteria-rich surface film, but insufficient to lift enough sediment to increase measured turbidity significantly. Hydrodynamic modeling results indicate that channel velocities in a tide-restored river would be insufficient to resuspend sediment (see below).

Effects of Tidal Restoration

Besides dilution (Fig. 7), other factors associated with restored tidal flow would depress coliform concentrations even more in a tide-restored Herring River estuary. Restoration will cause a radical change in water chemistry (Portnoy 1999, Spaulding & Grilli 2001). As mentioned, the survival time of enteric bacteria is reduced by high pH (Carlucci & Pramer 1960) and high salinity (Goyal et al. 1977, Bordalo 2002). With tidal restoration, low-tide salinities just above and below the dike structure would increase from the present 20–25 ppt to 30–32 ppt (Spaulding & Grilli 2005), decreasing coliform survival. The resaturation of current acid-sulfate soils (Portnoy & Giblin 1997b) with seawater would rapidly (weeks to months) restore circum-neutral pH of marsh peat and receiving waters (Portnoy & Giblin 1997a). In addition, the physical alternative for restoration comprises a wide culvert, which will not only increase high tide heights but will also improve low-tide drainage (Spaulding & Grilli 2005), greatly improving tidal flushing with generally oxygen-saturated seawater; this should alleviate summertime oxygen stress in the diked estuary (Portnoy 1991). All of these water-quality factors should drive bacteria concentrations below that expected with simple tidal dilution. Meanwhile, although the hydrodynamic modeling indicated that channel velocities would not increase enough to resuspend potentially FC-rich sediment (Spaulding & Grilli 2005), somewhat increased flood-tidal flow velocity and much-increased tide heights would shift fine-sediment deposition from river channels to the wetland surface, where both dessication and light would depress FC survival (Bordalo et al. 2002). Finally, under existing tide-restricted conditions, Herring River sediments with highest FC content are flooded throughout the tidal cycle; tide restoration and better low-tide drainage would expose these sediments to solar UV radiation, further reducing viable bacteria (Fujioka et al. 1981, Sinton et al. 2002) on or near the sediment surface.

Other Study Sites

Although many other differences among Pamet River and Hatches and East Harbors could have affected enteric bacteria, results were consistent with relationships observed at Herring River between the degree of tidal restriction and microbiological water quality. All three tide-restricted sites, except recently tide-

restored Hatches Harbor, have established conditions that promote FC retention and survival: specifically depressed tidal flushing, water-column salinity, pH, aeration and increased deposition of fine sediments in main creek channels.

CONCLUSION

The source of fecal bacteria in outer Cape Cod's restricted, but otherwise mostly undeveloped, estuarine watersheds is probably wildlife. Because land use has changed little in many decades, and it is not likely to change significantly in terms of wildlife use of coastal wetlands, attempts to limit this coliform source are unlikely to succeed. Even if it is assumed that FC from wildlife is a good indicator of the presence of human pathogens (Griffin et al. 2001), there would probably be strong public opposition to discouraging wildlife activity. Also, waterfowl (at least) are most abundant during winter when shellfish harvest is limited (Valiela et al. 1991, Weiskel et al. 1996). As an alternate approach, this study suggests that the hydrologic restoration of tide-restricted salt marshes may help to improve shellfish-water quality among its many other social and ecological benefits (Roman et al. 1995, Burdick et al. 1997).

Regardless of the bacterial source, tide restriction has created water and sediment conditions behind dikes that favor coliform accumulation and survival. With limited flushing by relatively coliform-free Cape Cod Bay water, ebb tides carry bacteria-laden Herring River water to downstream shellfish beds, closing many hectares of oysters and threatening extensive hard-clam aquaculture. In addition, the dike's restriction on semidiurnal flooding with aerobic seawater has caused oxygen stress and low salinity; and effective peat drainage has led to high acidity—all of which extend bacteria survival times.

Given observed spatial and temporal (tidal) patterns of water-column fecal coliform abundance in the diked Herring River, the projected physical and water-chemical effects of tidal restoration should cause a substantial improvement in bacteriological water quality. Aside from increases in salinity, dissolved oxygen and pH that should reduce enteric bacteria survival, dilution alone, from radically increased intertidal volume, should reduce coliforms to concentrations that allow reopening of oyster beds closed for many decades. In addition, increased sediment exposure during predicted lower low tides would further reduce bacteria survival. Assuming no new major source of FC within the river system, increased dilution of river water would confer even more protection on hard-clam aquaculture beds from bacterial contamination.

The relationships among tidal restrictions, water quality and public health bacteria should be studied in other coastal ecosystems, particularly those experiencing shellfish-bed closures. These results suggest that hydrodynamic and hydrographic alterations may contribute substantially to coastal coliform contamination even without dense urbanization.

ABSTRACT Several molecular diagnostic assays have been developed in an attempt to replace the traditional Ray's Fluid Thioglycollate Medium (RFTM) assay for detection and quantification of *Perkinsus marinus* in oysters. Real-time PCR technology is a state-of-the-art method currently used to diagnose disease intensity in vertebrates. We developed a simple (two-reagent) real-time PCR assay to quantify *P. marinus* (PMAR) and *Perkinsus* spp. (PERK) in oysters, using TaqMan® assays designed with Minor Groove Binder (MGB) probes on an Applied Biosystems 7500 Real-Time PCR System. Both PERK and PMAR assays demonstrate strong correlations ($R^2 \geq 0.99$) between parasite cell density and real-time PCR threshold cycle (C_T) with amplification efficiencies $\geq 99\%$. The PERK assay results in similar amplification plots for the three species tested (*P. marinus*, *P. olseni* and *P. chesapeakei*), whereas the PMAR assay detects only *P. marinus*. A strong correlation ($R^2 > 0.90$) was found between infection level determined by the traditional RFTM method and quantification by real-time PCR, based on internal standards prepared from *P. marinus* spiked oyster tissue. The PCR assays also detected *Perkinsus* in oysters diagnosed as negatives using the traditional method, suggesting that the described assay may be more sensitive. These assays provide a nonsubjective, specific and accurate quantification of *P. marinus* in oyster tissues and thus could potentially replace the traditional method in some applications.

KEY WORDS: TaqMan®, real-time PCR, *Perkinsus*, oysters

INTRODUCTION

The long and continuing decline of eastern oyster (*Crassostrea virginica*) fisheries has been partly attributed to the persistent and oftentimes catastrophic effects of the diseases MSX (caused by *Haplosporidium nelsoni*) and Perkinsosis (caused by *Perkinsus marinus*). The ability to develop and execute effective management strategies has necessitated the development of efficient tools by which the prevalence and intensity of infections can be evaluated in natural populations. Traditionally, *P. marinus* infections have been assessed using the Fluid Thioglycollate Medium (RFTM) assay (Ray 1966). This method involves the culture of the parasite prior to staining and visualization, and thus it necessitates that the parasite be viable at the time of processing. Several molecular assays have been developed that not only streamline the diagnostic process but also can be used to assess prevalence of *Perkinsus* spp. in archived or frozen tissues, which could expand our understanding of the patterns in disease occurrence and the environmental factors that may influence them (see review by Villalba et al. 2004). Primers that target either the nontranscribed spacer (NTS) or internal transcribed spacer (ITS) regions of the ribosomal RNA (rRNA) gene complex have been used in *P. marinus* specific PCR assays (Marsh et al. 1995, Robledo et al. 1998, Audemard et al. 2004). General primers have also been designed to detect virtually all *Perkinsus* species (Casas et al. 2002).

Real-time PCR technology is a state-of-the-art method used to quantify initial target levels of RNA and DNA and has gained wide use in clinical laboratory diagnostics (Kaltenboeck & Wang 2005). Whereas standard PCR methods analyze product formation during the plateau phase (or endpoint), real-time PCR quantification occurs during logarithmic amplification of the target, which can be more accurately related to initial target concentration. This difference is critical for the development of assays comparable to the

RFTM method, which provides not only presence/absence of the parasite but also infection intensity. The utility of real-time PCR approaches in quantifying *Perkinsus* spp. was demonstrated by Audemard et al. (2004), who reported real-time PCR methods for the detection and quantification of *Perkinsus* in environmental samples.

Here, we report the development of a simple, efficient real-time PCR assay to quantify *P. marinus* and *Perkinsus* spp. cell density in oyster tissues using TaqMan® Assays, designed with Minor Groove Binder (MGB) probes, detected on an Applied Biosystems 7500 Real-Time PCR System and analyzed with SDS software. This real-time PCR method overcomes a common problem in real-time PCR protocols, specifically the need for efficient amplification in order for the assay to be accurate in the quantification of the target. The TaqMan® Assays pair specific forward and reverse PCR primers to amplify a relatively short amplicon (<150 bp). The targeting of a small amplicon serves to one, increase amplification efficiency and two, reduce false negatives that may result from DNA rearrangement events that can occur within larger target regions, which is particularly important when targeting the NTS or ITS regions. The specificity of the real-time PCR measurement is increased with the TaqMan® internal probe prepared with a 5' fluorescent reporter dye, a 3' quencher and an MGB tail to allow increased stringency (Kutyavin et al. 2000). The fluorescence of unbound probe is quenched until the probe binds to the amplicon and the 5' exonuclease activity of *Taq* polymerase permanently releases the 5' fluorescent signal. If the probe is released without having been cleaved, as in the case of mismatches encountered during the exonuclease activity, the two ends will resume their close association and no signal will be delivered.

The increased specificity provided by the inclusion of TaqMan® probes allows discrimination of comparatively minor differences between sequences. The combination of these factors (short target amplicons, specific probes) results in a sensitive, specific and accurate determination of *P. marinus* and *Perkinsus* spp.

cell density in oyster tissue that not only increases the efficiency of diagnosing *Perkinsus* spp. in oysters but also provides a new tool that may extend our understanding of this important oyster pathogen.

MATERIALS AND METHODS

In vitro Cultures

P. marinus (P-1) cultures were obtained from J. La Peyre (Louisiana State University) and maintained as previously described (Gauthier & Vasta 1995). Cultured *P. olseni* and *P. chesapeaki* were obtained from the American Type Tissue Culture Collection (ATCC 50984 and 50807, respectively) and were used to test assay specificity.

TaqMan® Assay Design

The assays were designed and synthesized as Custom TaqMan® Gene Expression Assays (Applied Biosystems, Foster City, CA) and the target sequences for the designs were submitted after having been formatted with their File Builder software.

Two target sequences were chosen for assay design (Fig. 1), both within the ITS region previously targeted by Casas et al. (2002), and referenced by Audemard et al. (2004). After aligning these regions with similar regions from other *Perkinsus* species (obtained from GenBank), one 231 bp region was identified that appears to be conserved across all species within this genus, and the *Perkinsus* spp. specific (PERK) assay was designed to anneal within this region. The second target sequence was a region that appears to be conserved in all *P. marinus* records but contains a higher frequency of substitutions relative to other species. The first *P. marinus* specific (PMAR) assay was designed to anneal within this region. *P. olseni* was identified as having the most similar sequence in the PMAR region and was chosen for testing the specificity of the PMAR assay despite the low probability of its occurrence in local oysters. Other species, such as *P. chesapeaki*, are considered more likely to coinfect oyster populations in North Carolina but exhibited greater differentiation relative to *P. marinus*.

Although the PERK assay efficiently reported all *Perkinsus* species tested (see results) and the first PMAR assay efficiently reported *P. marinus*, the initial PMAR assay exhibited cross-reactivity with *P. olseni* samples. This could be attributed to the fact that there was only a single-base mismatch in the probe bind-

ing site in *P. olseni* and only a single-base mismatch in each of the two primers. To enhance the specificity, two of the oligonucleotides in the PMAR assay were redesigned. The first was a slight shift of the reverse primer to incorporate one additional base mismatch, whereas retaining its melting temperature (T_M) of about 60°C. The other modification was to reduce the T_M of the probe. Ideally the MGB probes are designed to have a T_M of 70°C (Applied Biosystems, Foster City, CA). However, to provide greater discrimination between a perfect match to *P. marinus* and the slight mismatch to *P. olseni*, the probe was designed with a T_M of about 66°C. The changes in the PMAR primers and probes did not increase the potential for cross reactivity with the other *Perkinsus* species. For example, when compared with the *P. chesapeaki* sequence, the new PMAR forward primer contained 4 mismatched base pairs, the reverse primer contained five mismatched base pairs, and the probe contained six mismatched base pairs—more than sufficient to avoid the generation of a false positive.

Preparation of *P. marinus* Standards for Real-time PCR

Cell density of *P. marinus* stock culture was determined by triturating cells through a 25-gauge needle and 5-mL syringe to break-up clusters prior to performing replicate hemocytometer counts. Replicate preweighed uninfected oyster mantle tissue samples (courtesy of Horn Point Laboratory, University of Maryland) were inoculated ("spiked") with 5, 50, 500, 5,000 or 50,000 *P. marinus* cells in a 10-μL volume of culture medium for the preparation of parasite cell density standards (parasites/g wet weight oyster tissue). These spiked tissue samples were immediately lysed and DNA extracted as described below.

DNA Extractions

Oyster tissue samples were resuspended in 400 μL PureGene Cell Lysis Solution (D-5002) along with 2 μL of a 20-μg/mL stock solution of proteinase K and incubated at 55°C overnight or until all tissue was dissolved. Solutions were allowed to reach room temperature prior to the addition of 140-μL PureGene Protein Precipitation Solution (D-5003), vortexed vigorously for 20 sec and placed on ice for 5 min. Tubes were centrifuged at top speed on a microcentrifuge for 5 min and supernatant transferred to a clean labeled tube. The DNA was precipitated with the addition of 400-μL 100% isopropanol then gently inverted 50 times prior to centrifugation for 5 min. The DNA pellet was washed with 400-μL 70% ethanol and allowed to air dry prior to the addition of 35-μL double deionized water (ddH₂O). DNA concentration (μg/μL = A260 nm × 0.05 × dilution factor) was determined on a Genesys 8 spectrophotometer and all samples were adjusted to 100 ng/μL. The 260-nm/280 nm absorbance ratio was used to determine the purity of DNA.

TaqMan® Reagents

The PERK specific primer/probe mix containing 18 μM each of forward and reverse primers and 5-μM TaqMan® probe, which was obtained as a 20× stock solution (ABI 4331348, Applied Biosystems, Foster City, CA). The PMAR specific primer/probe mix was prepared manually by diluting each 100-μM primer (ABI 185312336–1,2) and 100-μM probe (ABI 185312336) to 18 μM and 5 μM, respectively for a 20× stock solution. The TaqMan® Universal PCR MasterMix (ABI 4324018) containing AmpliTaq Gold DNA Polymerase, AmpErase without UNG, dNTPs with dUTP, and buffer components optimized as a 2× solution.

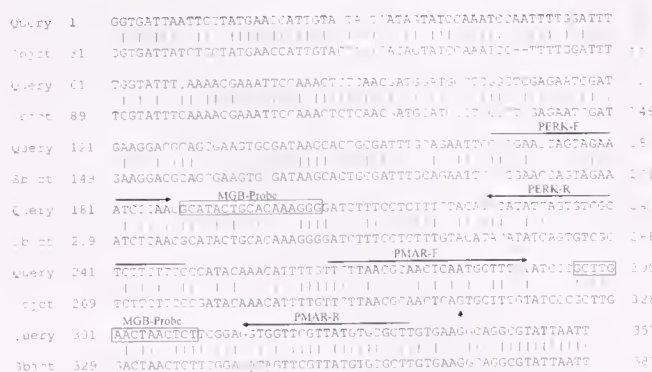

Figure 1. Primer and probe design for PERK and PMAR real-time PCR assays within the ITS region of *Perkinsus* spp. rRNA. The top sequence is *P. marinus* and the bottom sequence is *P. olseni*. Arrows highlight mismatches between sequences.

Real-time PCR

Reagents were added in the following proportions to each well of 96-well optical reaction plates (ABI 4306737): 12.5- μ L MasterMix, 1.25- μ L prime/probe, 9.25- μ L ddH₂O, and 2- μ L of template (100 μ g/ μ L) for a 25- μ L reaction volume. Plates were sealed with ThermalSeal RT (Excel Scientific, Inc). Real-time PCR was conducted on an ABI 7500 Real-Time PCR System using the ABI 7500 System SDS Software using the default temperature program (95°C/10 min; 40 cycles of 95°C/15 sec followed by 60°C/1 min) for a total run time of 1.5 h.

Specificity and Sensitivity of PERK and PMAR Assays

The specificity of PERK and PMAR primer/probe reagents was determined by conducting real-time PCR as described above on separate aliquots of 10-ng DNA from *P. marinus*, *P. olseni* and *P.*

chesapeakei and observing each of the amplification plots relative to nontemplate controls. The sensitivity of the two assays was determined separately on 10-fold serial dilutions of *P. marinus* target DNA (10 pg-0.001 fg) in the presence of 100 ng oyster DNA.

Quantification of *Perkinsus* spp. in Naturally Infected Oysters

A comparison was made between *P. marinus* infection intensity determined by real-time PCR and the traditional RFTM assay using mantle tissue. Thirteen intertidal oysters were collected from Masonboro Sound at the UNCW Center for Marine Science (30 ppt, 24°C ambient conditions). Two ~5mm² pieces of mantle tissue were removed and placed in either 10-mL RFTM medium with antibiotics for the traditional method (Ray 1966, Mackin 1962, Craig et al. 1989) or microcentrifuge tube for real-time PCR analysis.

Determination of parasite cell density in unknown samples was

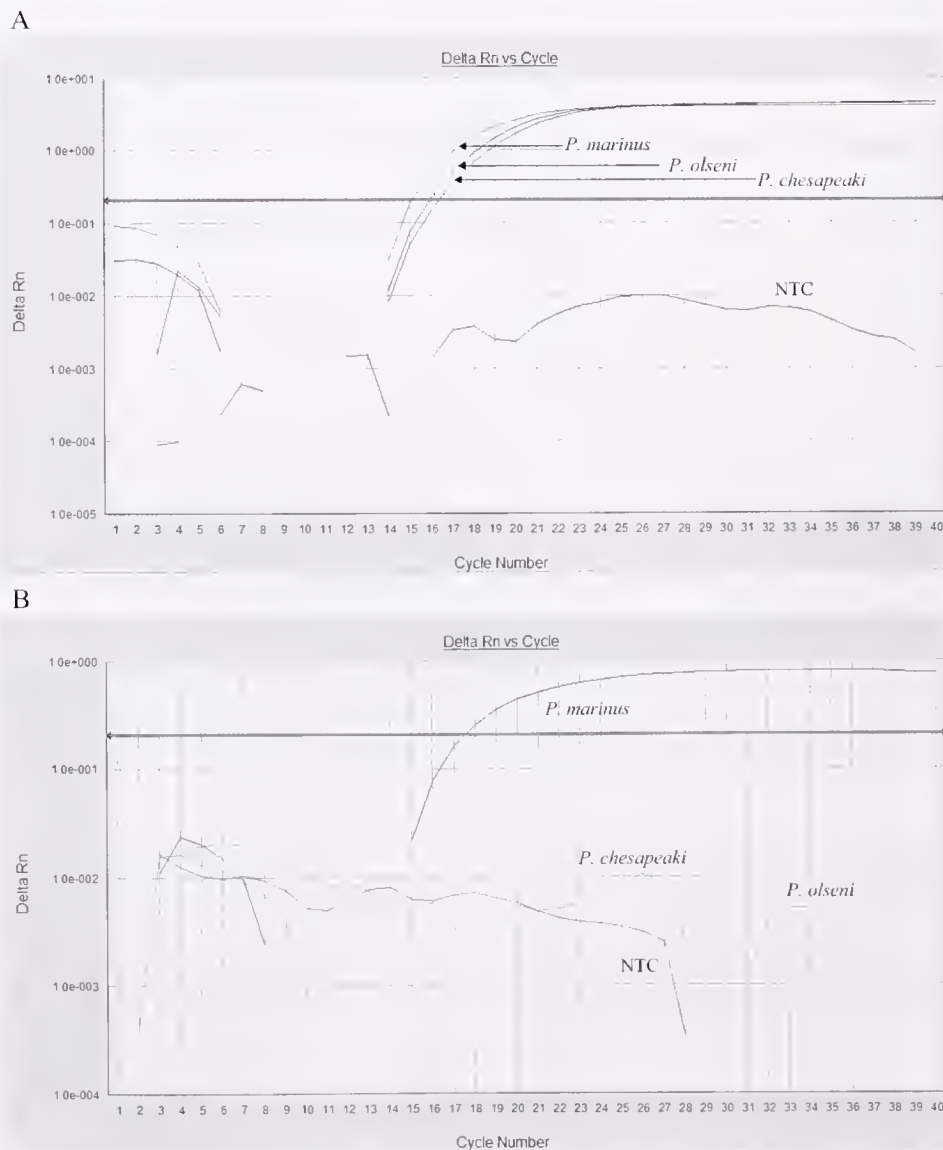

Figure 2. Specificity of PERK (A) real-time PCR assay demonstrated by amplification of *P. marinus*, *P. olseni* and *P. chesapeakei* and PMAR (B) real-time PCR assay demonstrated by amplification of *P. marinus* but not *P. olseni* or *P. chesapeakei*. NTC = nontemplate control. Positive amplification is indicated when Delta Rn values exceed the threshold indicated by the horizontal line. Delta Rn represents the change in fluorescent signal produced from the cleaved TaqMan[®] probe, reporting successful binding of the probe to the target sequence.

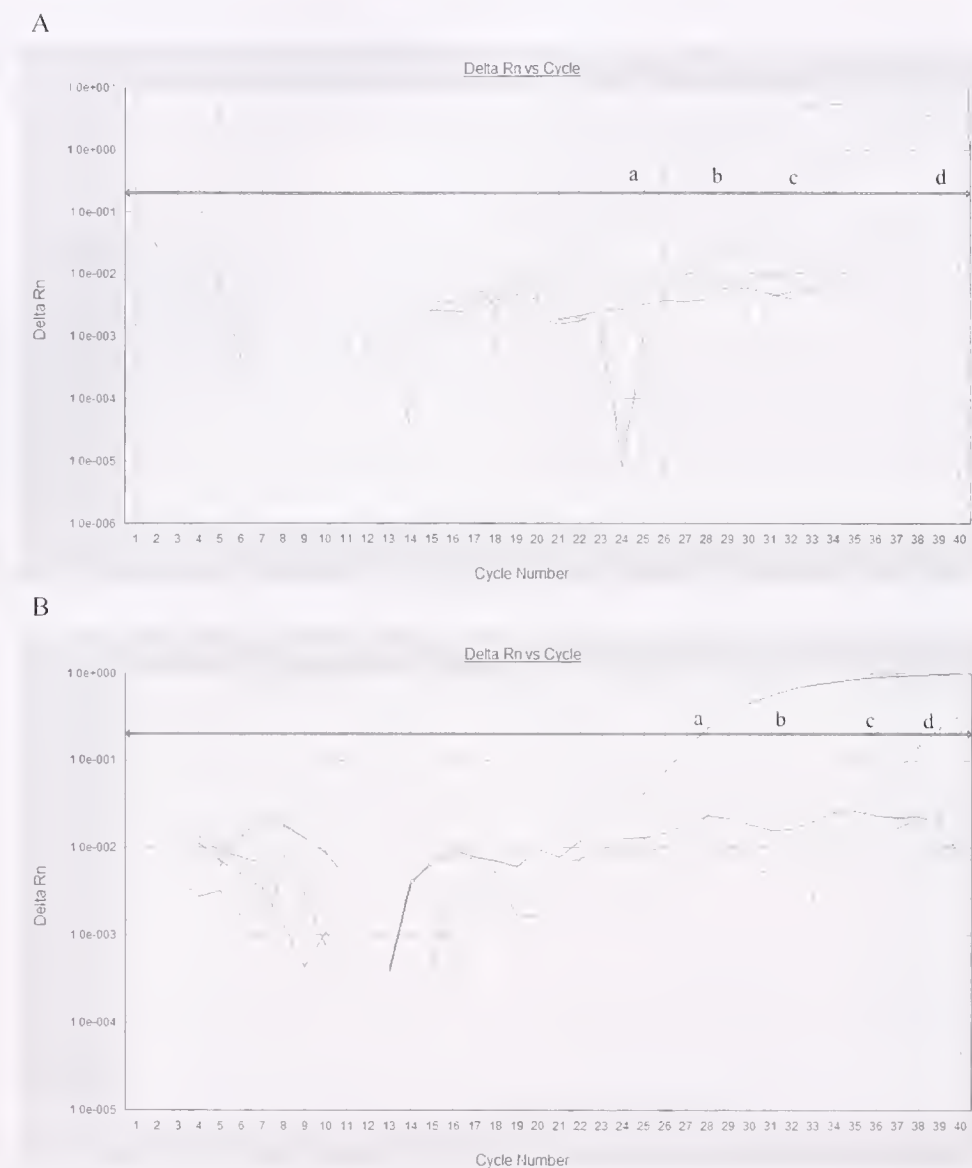

Figure 3. Detection limit (10 fg) of PERK (A) and PMAR (B) real-time PCR assays demonstrated by amplification plots for a 10-fold serial dilution of *P. marinus* DNA in the presence of 100 ng of uninfected oyster DNA. a = 10 pg; b = 1 pg; c = 0.1 pg; d = 10 fg. Positive amplification is indicated when Delta Rn values exceed the threshold indicated by the horizontal line. Delta Rn represents the change in fluorescent signal produced from the cleaved TaqMan[®] probe, reporting successful binding of the probe to the target sequence.

accomplished by including three or more standards (described above) for each real-time PCR run. The ABI 7500 software automatically plots the relationship between cell density and threshold cycle (C_T) and converts C_T values of unknowns to parasite cell density. The C_T value represents the number of cycles required for target amplification to reach the exponential phase and is therefore inversely related to initial target concentrations.

Statistical Analysis

Linear regression analysis was conducted to determine the relationship between parasite cell density and C_T value and between real-time PCR determination of infection intensity and semiquantitative estimates using the RFTM method.

RESULTS

Specificity and Sensitivity of PERK and PMAR Assays

The PERK assay resulted in similar amplification plots for *P. marinus*, *P. olseni* and *P. chesapeakei* DNA (Fig. 2A), whereas the PMAR assay resulted in amplification of *P. marinus* but not *P. chesapeakei* or *P. olseni* (Fig. 2B). The sensitivity of the PERK and PMAR assays were similar, detecting down to 10 fg *P. marinus* DNA in the presence of 100-ng oyster DNA (Fig. 3).

Standard Curves for PERK and PMAR Assays

A strong correlation ($R^2 \geq 0.99$; $P < 0.0001$) was observed between *P. marinus* cell density in oyster tissue and C_T determined

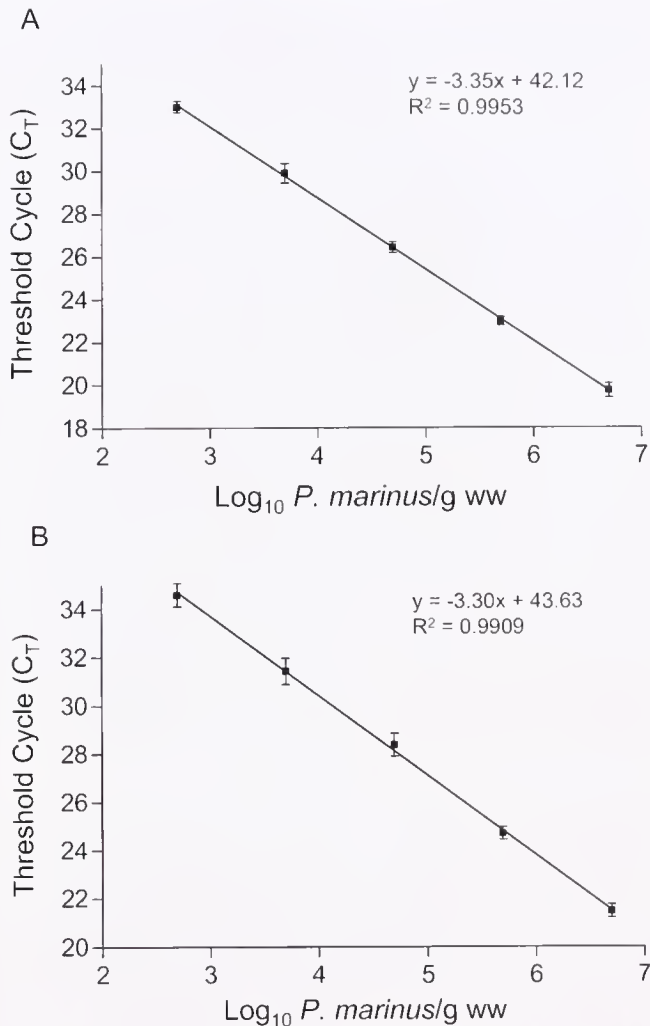

Figure 4. Standard curves representing relationship between parasite cell density of spiked oyster tissue (\log_{10} parasites/g wet weight oyster tissue) and threshold cycle (C_T) determined for the PERK (A) and PMAR (B) real-time PCR assays. (Mean \pm SE; $n = 2$)

by PERK and PMAR real-time PCR assays (Fig. 4). Amplification efficiency ($[10^{(-1/\text{slope})} - 1]$) for both assays was determined to be $\geq 99\%$. These parasite cell density standards were included in all PCR runs to determine infection intensity in field collected oyster tissue described later.

Quantification of *P. marinus* in Naturally Infected Oysters

A strong correlation ($R^2 \geq 0.90$; $P < 0.0001$) was found between infection intensity determined by the traditional RFTM mantle tissue assay and both PERK and PMAR real-time PCR assays based on internal standards prepared from *P. marinus* spiked oyster tissue (Fig. 5). Both PCR assays detected parasites in oysters (2 out of 13) diagnosed as uninfected by the traditional RFTM method. All 13 oysters tested positive by PCR, but only 11 tested positive by the RFTM method.

DISCUSSION

The results presented suggest that the TaqMan® MGB approach provides an efficient and accurate method for not only quantifying the prevalence and intensity of *P. marinus* infections

Figure 5. Relationship between the traditional RFTM assay for determining *Perkinsus* spp. infection intensity and PERK (A) and PMAR (B) real-time PCR assay determination of parasite cell density in mantle tissue.

but also a tool for investigating patterns of coinfection involving other species of *Perkinsus*. The combination of the genus-specific (PERK) that targets an 86 bp region and the species-specific (PMAR) assays that targets a 72 bp region can be used to evaluate the extent to which positive *Perkinsus* diagnosis could be attributed to species other than *P. marinus*. Although not all reported *Perkinsus* species were tested, the PERK assay recognized both *P. marinus* and *P. chesapeaki*, which share the lowest sequence identity within the target region, based on the data available in GenBank. The specificity of the PMAR assay is demonstrated by the lack of recognition for *P. olseni*, the species with the greatest sequence identity to *P. marinus* within the target region.

Our results demonstrate that the PCR assays are an accurate alternative to the traditional mantle smear RFTM method for the assessment of disease intensity. Parasite cell density standards, prepared by spiking oyster tissue samples of known wet weight with known numbers of cultured *P. marinus*, were used to determine parasite density in naturally infected oysters and these estimates correlate well with those obtained using the RFTM method

on the same oysters. Further, the linear relationship between the two methods allows us to convert the PCR data to familiar terms (Mackin Scale) if needed. Such agreement between methods allows for integration of data sets that rely on the different methods.

The reliance of the assay on the relatively easy to sample mantle tissue is also advantageous. Research has shown that although mantle tissue can be used fairly accurately to assess disease prevalence and intensity in oyster populations (Bushek et al. 1994, Oliver et al. 1998), the traditional RFTM method is known to result in false negative diagnoses at low infection levels (Choi et al. 1989). A major advantage of the PCR approach is the increased sensitivity with which mantle tissue samples can be analyzed, thus minimizing the likelihood of a false negative diagnosis. In this study, PERK and PMAR assays detected infections in oysters that were diagnosed as negative by the RFTM method.

Although the traditional RFTM method is approximately 3-fold less expensive, there are several advantages and particular applications of the real-time PCR assays: First, they can be used to distinguish between *P. marinus* and other *Perkinsus* spp. The ability to determine the extent to which infected oysters harbor more than a single species is of considerable interest. Nonspecific quantification could result in overestimation of *P. marinus* levels in areas where different species co-occur. Whereas the small numbers of natural oysters evaluated during this study exhibited similar infection intensities when tested with the generic and specific assays (suggesting an absence of multiple infections), a more substantial study would provide a more definitive answer to this question. Further, the ability to specifically attribute infections to *P. marinus* may facilitate the evaluation of other species to act as potential reservoirs.

A second advantage is that the PCR assays eliminate the subjectivity associated with estimation of infection intensity using a semiquantitative rating system. The potential for subjective error poses a problem when comparing year-to-year samples, particularly when there are multiple investigators involved. Third, the assays are extremely sensitive, detecting down to 10 fg of *P.*

marinus DNA in the presence of 100 ng oyster DNA. This sensitivity is likely to result in a more accurate assessment of disease prevalence and intensity. Fourth, the assays provide an accurate, quantitative measure of parasite cell density in oyster tissue samples. The linear relationship between known parasite cell density and C_T is used to quantify infection level in unknown tissue samples. Fifth, these assays can be accomplished in 1–2 days if needed as opposed to 5–7 days required for the RFTM assay. The assays are also relatively simple molecular protocols with only two reagents involved in setting up the PCR reaction. Lastly, the assays can make use of frozen samples or archived DNA, whereas the RFTM method requires that parasites be kept alive until processing. This attribute is allowing us to assess oyster disease patterns in North Carolina over the past several years from archived samples. Oyster tissue can also be sent through the mail in cell lysis solution without refrigeration for processing elsewhere.

The advantages associated with the adoption of real-time PCR strategies for the quantification of Perkinsosis in oysters may be offset in part by the greater expense associated with such techniques. Further refinement and automation of the assay will undoubtedly reduce the costs, and the advantages of the real-time assays will, in some cases, more than justify the additional costs. The linear relationship between the PCR assay determination of parasite cell density and the traditional semiquantitative rating scale allows us to relate results from the two methodologies.

ACKNOWLEDGMENTS

The authors thank J. La Peyre for providing initial *P. marinus* cultures and S. Alexander for hatchery reared uninfected oysters; T. Alphin and S. Colosimo for their advice and help with oyster field samples and the DNA core facility for use of its ABI 7500 Real-Time PCR System. The comments of two anonymous reviewers improved the manuscript. This research was funded in part by the Marine Biotechnology program at the UNCW Center for Marine Science.

ABSTRACT Shellfish including oysters (*Crassostrea gigas*), cockles (*Cerastoderma edule*) and mussels (*Mytilus edulis*), have previously been described as an important source of thermophilic campylobacters, with the potential of causing acute bacterial gastroenteritis in humans. Previous genotyping studies employing the polymerase chain reaction–restriction fragment length polymorphism (PCR-RFLP) typing, based on the flagellin (*flaA*) gene have been unable to generate an amplicon for the urease-positive thermophilic *Campylobacter* (UPTC), which are the predominant taxa associated with shellfish, largely caused by sequence diversity between the UPTC group and *C. jejuni*. Hence the aim of this study was to develop a modified PCR-RFLP genotyping assay, employing polymorphisms within the flagellin (*flaA*) gene of UPTC organisms, which would now allow the successful amplification and typing of previously nontypable UPTC isolates obtained from natural marine environments. A novel primer pair (UPTC *flaF*/UPTC *flaR*) was designed based on conserved regions within the *flaA* gene locus of UPTC organisms to generate a 1,358 bp amplicon for all UPTC organisms tested. RFLP analysis with *DdeI* in combination with computational analysis of genetic relatedness using BioNumerics software demonstrated the presence of four distinct *flaA* genotypes, among the seven UPTC isolates. In conclusion, this study describes a PCR-RFLP method, based on modified primers from UPTC *flaA* gene sequences that may be successfully applied to examine subspecies relatedness of UPTC organisms from natural environments, including shellfish.

KEY WORDS: *Campylobacter jejuni*, DNA, flagellin (*flaA*), genotyping, PCR, shellfish, urease-positive thermophilic *Campylobacter* (UPTC)

INTRODUCTION

Thermophilic *Campylobacter* spp., including *C. jejuni*, *C. coli* and *C. lari*, are the most common cause of acute bacterial gastroenteritis in the developed Western world (Altekruse & Tollefson 2003). In Northern Ireland, laboratory confirmed isolates account for an approximate annual total of 800–1,000 cases, representing an attack rate of 59 cases per 100,000 individuals (Anon, 2002). In general, most *Campylobacter* infections are believed to be transmitted zoonotically to humans from various animal reservoirs, including poultry, cattle, pigs and from household pets, including cats and dogs, although the epidemiology and routes of transmission are still not completely understood. In addition, various reports have described the presence of thermophilic *Campylobacter* in shellfish, including oysters (*Crassostrea gigas*), cockles (*Cerastoderma edule*) and mussels (*Mytilus edulis*) (Wilson & Moore 1996, Endtz et al. 1997). Given that shellfish may be cultured and harvested in marine waters that are contaminated with agricultural run-off or with human sewage, shellfish concentrate fecal pathogens, including campylobacters

mainly in their gill tissues and such produce may be a hazard to public health, particularly if (1) they are consumed raw; (2) are eaten following only a partial cooking or (3) are allowed to cross-contaminate other foods and utensils in the kitchen, where they are being prepared.

Various previous studies have demonstrated problems in the genotyping of the most common form of *Campylobacter* in shellfish, mainly the urease-positive thermophilic *Campylobacter* (UPTC) (Moore et al. 2003, Sekizuka et al. 2004), whereby these isolates failed to be typed using conventional flagellin (*flaA*)-based restriction fragment length polymorphism (RFLP) analysis, as described originally by Nachamkin et al. (1993). This inability to generate a PCR amplicon with the UPTC organisms was most likely to be caused by significant mutations in the flagellin gene structure in the UPTC organisms, compared with *C. jejuni*, from where the PCR primers were originally designed.

Hence, it was the aim of this study to develop a modified PCR-RFLP genotyping assay, using polymorphisms within the flagellin (*flaA*) gene of UPTC organisms as an epidemiological marker, which would now allow the successful amplification and typing of previously nontypable UPTC isolates obtained from shellfish and environmental water sources.

MATERIALS AND METHODS

Design of Modified flaA Primers

Two novel PCR primers were designed and designated as UPTC *flaF* (forward primer) and UPTC *flaR* (reverse). The *flaA* gene sequences of six UPTC isolates, which had been recently

published, including UPTC AB07058, AB073915, AB073916, AB073917, AB073918 and AB080202 (GenBank Accession number), were aligned employing the Clustal alignment tool in combination with DNASTAR software (DNASTAR Inc, Wisconsin, USA). Conserved sites were selected (Fig. 1) and contained the following sequences UPTC *flaF* 5'-ATT AAC ACA AAT GGT

(a). Position of UPTC *flaF* (forward primer)(b). Position of UPTC *flaR* (reverse primer)

Figure 1. Alignment of the flagellin (*flaA*) gene locus in six isolates of urease-positive thermophilic *Campylobacter* (UPTC) showing (a) conserved nature of forward primer (UPTC *flaF*) and (b) conserved nature of reverse primer (UPTC *flaR*). UPTC isolates detail their GenBank accession numbers.

GCA TCT TTA AAT G-3', corresponding to base positions 10–37 in relation to UPTC AB080202 and UPTC *flaR* 5'-CTC TAA TTT GTG ATT CAG CAG CTT TAA CAT T-3', corresponding to base positions 1357–1327 in relation to UPTC AB080202. Amplification using these primers was estimated to generate a PCR amplicon of approximately 1,358 bp in length.

Source of UPTC Isolates Used in This Study

Seven isolates belonging to the UPTC biovar of *C. lari* were used in this study, including four wildtype isolates and three reference isolates, obtained from different environments and in different countries, as detailed in Table 1. In addition, *C. jejuni* ATCC33560 was also used in this study.

DNA Extraction

All isolates were cultured under microaerophilic conditions (5% v/v CO₂) for 48 h on Butzler selective medium, and their species designation was confirmed, as described previously (Moore et al. 2003). Bacterial genomic DNA was extracted in accordance with the method of Harrington et al. (1999) and resulting nucleic acid (DNA) was quantified and adjusted to yield a working concentration of approximately 1.0 µg/µL. Extracted DNA was stored frozen at –20°C until used and at 4°C thereafter.

PCR Amplification and Restriction Fragment Length Polymorphism (RFLP) Analysis

After PCR optimization, amplification was performed on all seven UPTC isolates, as well as with the *C. jejuni* isolate, as detailed in Table 1. Reaction mixes (25 µL) were set up as follows: 10 mM Tris-HCl, pH 8.3, 50 mM KCl, 2.5 mM MgCl₂, 200 µM (each) dATP, dCTP, dGTP and dTTP; 1.25U of *Taq* DNA polymerase (Takara Corp., Tokyo, Japan), 10 pmol (each) of the forward and reverse primers (i.e., UPTC *flaF*/UPTC *flaR*) as described above and 1 µL of DNA template. The reaction mixtures after a "hot start" were subjected to the following optimized thermal cycling parameters in a Perkin Elmer 9700 thermocycler: 96°C for 3 min followed by 40 cycles of 96°C for 1 min, 58.5°C for 1 min, 72°C for 2.5 min, followed by a final extension at 72°C for 10 min. During each run molecular grade water was included randomly as negative controls. After amplification, aliquots (15 µL) were removed from each reaction mixture and examined by electrophoresis (100 V, 60 min) in gels composed of 1.0% (w/v) agarose (L03, Takara Corp., Japan) in 0.5 × TBE buffer, stained with ethidium bromide (5 µg/100 mL). Gels were visualized under UV illumination using a gel image analysis system (Atta Image Saver, Atta Corp., Japan).

* UPTC, urease-positive thermophilic *Campylobacter*.

A restriction map was prepared from analysis of the 1,358 bp *flaA* fragment to estimate the optimal restriction enzymes(s) to use to detect polymorphisms in this fragment, using MapDraw software (DNASar Inc., Wisconsin, USA). After PCR amplification, resulting amplicons (10 µL) were digested to completion with the restriction endonuclease *Dde* I (10U) (cleavage site sequence CTGCA↓G; Toboyo Co. Ltd., Osaka, Japan), at 37°C for 4 h in the manufacturer's (H) buffer at the recommended concentration. Digested DNA fragments (15 µL) from the *Dde* I digestion were subjected to electrophoresis, as described earlier, with the exception that digested fragments were separated on a 2.5% (w/v) agarose gel and visualized, as detailed earlier.

Computer Estimation of Genetic Relatedness

Computer analysis of the RFLP banding patterns obtained was performed with the BioNumerics software package (Applied Maths, Kortrijk, Belgium). Initially, all RFLP banding patterns were normalized and all images were compatible with one another after normalization, and complete RFLP patterns were used for analysis. In general, bands were automatically assigned by the computer and were corrected manually after the original images were visually checked. Only clearly resolved bands were counted. The Pearson coefficient was used to analyze the similarities of the banding patterns. The unweighted pair group method with average linkages (UPGAMA) was used for cluster analysis and the cophenetic correlation coefficient for the whole dendrogram was calculated for estimation of the faithfulness of the cluster analysis, using the BioNumerics software.

RESULTS AND DISCUSSION

PCR amplification using the novel primer pair, UPTC *flaF*/UPTC *flaR*, allowed the reproducible generation of a *flaA* amplicon of approximately the expected size (*circa* 1,358 bp) for all UPTC isolates examined (Fig. 2). A slightly larger amplicon (*circa* 1,500 bp) was generated for *C. jejuni* ATCC33560 (data not shown). Restriction map analysis with *Dde*I demonstrated the presence of at least five restriction sites within the PCR amplicon, yielding fragments at positions 82, 155, 644, 885 and 910. Subsequent restriction of PCR amplicons demonstrated the presence of at least three bands, which were grouped into four banding profiles (genotypes), as determined by analysis by the BioNumerics software (Fig. 3).

Figure 3. Dendrogram derived from RFLP analysis with UPTC *flaF*/UPTC *flaR* primers targeting a 1,358 bp fragment of the flagellin (*flaA*) gene in seven isolates of urease-positive thermophilic *Campylobacter* (UPTC) (see Table 1). *flaA* PCR amplicons were digested to completion with *DdeI* restriction enzyme. The Pearson coefficient was used to calculate similarities and UPGAMA was used for cluster analysis with BioNumerics software (Applied Maths, Belgium).

Marine bivalve molluscs such as mussels (*Mytilus edulis*), cockles (*Laevicardium edula*), scallops (*Pecten maximus*) and oysters (*Crassostrea gigas*) are grown commercially in in-shore waters around Northern Ireland with an annual production and market value of 288.4 tons and £527,733 respectively. These shellfish feed by filtering plankton and detritus from large volumes of sea water, thereby concentrating gastrointestinal pathogenic organisms found in such waters, including *Campylobacter*, *Salmonella* and enteric viruses in their digestive system (Wilson & Moore 1996), which may be important vectors in the transmission of disease. The association between ingestion of raw shellfish and enteric diseases such as typhoid has been recognized and more recently, there has been several reports of shellfish-associated gastroenteritis with strong evidence for *Campylobacter* spp. as the etiologic agent. *Campylobacter* spp. have been found routinely in West Coast shellfish beds in the States of California, Oregon and Washington (Abeyta et al. 1993). Sample types included oysters, cockles, sediment, seawater, freshwater (streams and tributaries), bird excreta and cattle manure. *Campylobacter* spp. in the marine environment primarily comes from wild birds (Kapperud & Rosef 1983), farm runoff, surface water (Carter et al. 1987) and sewage bypasses (Jones 2001).

Urease-positive thermophilic *Campylobacter* (UPTC), a microaerophilic and Gram-negative bacterium, is an organism only identified relatively recently in England (Bolton et al. 1985). After the original descriptions of UPTC appeared, isolates of UPTC were reported in France, Ireland and The Netherlands, and UPTC strains have also recently been found in Japan (Matsuda et al. 1996). The original strains were isolated from river water, sea water, mussels and cockles. In 1988, Megraud et al. reported the first isolation of UPTC from human clinical infection, where these organisms were isolated from an appendix as well as from human feces (Megraud et al. 1988).

This group of organisms has been frequently found as the most frequent *Campylobacter* found in shellfish and waters (Wilson & Moore 1996).

The understanding of sources and means of transmission of UPTC organisms is important to help elucidate the epidemiology of these organisms in shellfish and the marine environment, as well as their potential transmission to humans. Consequently a reproducible, sensitive and well-standardized typing scheme is critical in the successful discrimination of such strains. Hence to elucidate the sources and modes of transmission of these organisms, it is

essential to use epidemiological typing methods that discriminate between different strains but which are reliable and reproducible in the recognition of similar strains.

This study was interested in the ability to genotype members of the UPTC group of organisms isolated in shellfish and was undertaken to develop a PCR-based method that would allow the differentiation between UPTC organisms at the subspecies level. Until now, employing the conventional PCR-RFLP (*flaA*) method, as described originally for the subspecies differentiation of clinical *C. jejuni*, has not been successful in its application with the UPTC organisms (Moore et al. 2003). Furthermore, because this method is widely used for other campylobacters, it was important to develop it further, so that it may be used successfully with this group of organisms. Previous inability to generate a PCR amplicon using the Nachamkin *flaA* primers suggested that the UPTC organisms had an altered flagellin gene arrangement compared with *C. jejuni*, with various mutations at the original primer sites. Subsequently, we have previously reported this altered flagellin gene rearrangements in UPTC, through the sequencing and analyses of the *flaA* gene of several UPTC wildtype and reference strains (Sekizuka et al. 2004). Hence, it was the aim of the current study to use this sequence data from UPTC organisms and design a modified assay that would allow the successful amplification of these organisms, helping facilitate their subsequent subspecies analyses.

After the development of a successful and reproducible PCR-RFLP system, employing the newly described primer pair (UPTC *flaF*/UPTC *flaR*), we wished to establish proof-of-principle for this technique in demonstrating the application of this method to a small collection of UPTC isolates obtained from the natural environment. Application of this technique to this small collection of isolates demonstrated genetic variability at the *flaA* locus between these isolates (Fig. 3). Shellfish growing in relatively shallow marine waters, including inshore waters, may be contaminated with campylobacters from several sources, in particular, effluent from agricultural run-off and human sewage. In addition, they may become contaminated because of fecal deposition of UPTC from wild birds, including members of the gull (*Larus*) family. In this study, genotypic analysis demonstrated the presence of the same genotype of UPTC in shellfish isolated from the natural environment, located approximately 10–30 kilometers from each other, with no sharing of the same watertable. This may suggest that gulls may have been responsible from the transmission of the same

genotype of UPTC between the two sites and hence acted as a vector of transmission of this particular genotype.

In conclusion, this study describes a PCR-RFLP method, based on modified primers from UPTC *flaA* gene sequences, that may be successfully applied to examine subspecies relatedness and routes of transmission of UPTC isolated from shellfish, so that we are better informed as to how these become contaminated to suggest intervention controls that would help reduce the loading of these shellfish with campylobacters. Further work is now required to establish routes of transmission of UPTC organisms from the environment to shellfish employing this modified technique.

THE EFFECTIVENESS OF HEAT, COLD AND 6-DIMETHYLAMINOPURINE SHOCKS FOR INDUCING TETRAPLOIDY IN THE KURUMA SHRIMP, *MARSUPENAEUS JAPONICUS* (BATE)

M. J. SELLARS,^{1,2,3*} F. E. COMAN,^{1,2} B. M. DEGNAN³ AND N. P. PRESTON^{1,2}

¹CSIRO Food Futures National Research Flagship; ²CSIRO Marine Research, 233 Middle Street, Cleveland, Qld, 4163, Australia; ³School of Integrative Biology, The University of Queensland, Brisbane, Qld, 4072, Australia

ABSTRACT In this study tetraploid *Marsupenaeus japonicus* (Bate) embryos were produced by preventing the first division in mitosis. The effectiveness of temperature and chemical shocks for producing tetraploid *M. japonicus* were assessed when applied at different times postspawning and for different durations. Tetraploid *M. japonicus* embryos (spawned at 27°C) were produced by heat shocks at 35°C and 36°C in three and eight spawning samples respectively, and a cold shock at 5°C in a single spawning sample. All temperature shocks inducing tetraploidy were applied 18–23 min postspawning for a 5–10 min duration. The percentage of spawnings successfully inducing tetraploid embryos (i.e., frequency of induction) ranged from 33.33% to 66.67% for the 21, 22 and 23 min postspawning heat shock treatment regimes. The percentage of tetraploid embryos within an induction (i.e., induction rate), as determined by flow cytometry, ranged from 8.82% to 98.12% (ave. \pm S.E.) ($34.4 \pm 21.4\%$) for the 35°C shock treatments, from 13.12% to 61.02% ($35.0 \pm 5.0\%$) for the 36°C shock treatments and was 15% for the 5°C cold shock treatment. No tetraploids were produced for spawnings that received heat shocks above 36°C or below 35°C, or for cold shocks above 5°C for any of the tested postspawning treatment and duration times. Chemical shock with 150 μ M 6-dimethylaminopurine did not result in tetraploid *M. japonicus* embryos at any of the tested postspawning treatment times and durations. Tetraploid *M. japonicus* embryos were nonviable, with no tetraploid larvae being detected by flow cytometry. Based on our results heat shocking of *M. japonicus* embryos at 36°C, 23 min postspawning for a 5–10 min duration is the most effective means to produce tetraploids through inhibition of the first mitotic division (taking into consideration the importance of frequency and induction rate equally).

KEY WORDS: *Penaeus japonicus*, polyploidy, shrimp, selective breeding, genetic protection

INTRODUCTION

In Australia, shrimp domestication and genetic improvement programs are most advanced for *Marsupenaeus japonicus* (Bate) (Preston et al. 2001). The development of selectively improved genotypes for over 10 generations and a live export market has prompted industry to seek mechanisms to sterilize stocks to prevent unlicensed breeding and the introduction of genetically improved strains into natural fisheries. Previous efforts to contain selectively bred *M. japonicus* have focused on inducing sterility via irradiation or triploidy. These techniques have yet to prove effective in providing guaranteed sterility in the target stocks. Irradiation has been reported to significantly impair the reproductive capacity of female *M. japonicus* when exposed to 20 gray and male *M. japonicus* when exposed to 10 gray (Sellars et al. 2005b). However, irradiation was not 100% effective at preventing the production of viable offspring. In comparison, successful triploidy induction through prevention of polar body II extrusion is 100% effective at preventing reproduction, however, inductions never result in 100% triploid progeny (Sellars et al. 2004, Norris et al. 2005).

Producing triploids by the mating of tetraploids with diploids may provide a solution to these variable induction rates, resulting in 100% triploid progeny. Triploid stocks have been produced through the mating of tetraploid and diploid broodstock in several marine species including Pacific oysters (*Crassostrea gigas*) (Guo & Allen 1994, Guo et al. 1996, Wang et al. 2002), oyster hybrids (*C. gigas* \times *C. ariakensis*) (Huayong & Allen 2002), Rainbow trout (*Oncorhynchus mykiss*) (Chourrout et al. 1986) and carp hybrids (*Crassius auratus* red var. \times *Cyprinus carpio* L.) (Liu et al. 2001).

However, production of viable tetraploids and their successful mating with diploids is a prerequisite for producing triploids in this manner.

There are many different methods for inducing tetraploidy in aquatic species, with the inhibition of an early embryonic developmental phase being critical to all. Because triploid *M. japonicus* do not produce viable gametes (Sellars et al. 2003, Preston et al. 2004, Sellars et al. 2004), there are only two possible ways to induce tetraploidy in this species: inhibition of polar body I extrusion during meiosis and prevention of the first division in mitosis. The prevention of polar body I extrusion has been reported to complicate subsequent chromosome segregation (Guo et al. 1992), and result in many different ploidy combinations including viable tetraploids. Inhibition of polar body I extrusion is difficult in some species because of the very short time frame in which the embryos must be treated and the fragile nature of the newly spawned embryos. In *M. japonicus* polar body I extrusion occurs at 4 min 10 sec postspawning at 27°C (Hudinaga 1941). Successful detection, collection, concentration and application of a shock to spawned embryos within this short time frame is a significant challenge. Only one reported study has attempted preventing polar body I extrusion in shrimp, however no tetraploids were successfully induced (Li et al. 2003).

Preventing the first division in mitosis is the alternative strategy that has been the focus of several previous attempts to induce tetraploidy in shrimp (Xiang et al. 1993, Peeters 1996, Li et al. 2003, Deoraj et al. 2005). Viable tetraploid shrimp, produced by inhibition of the first mitotic division, have only been reported in a single study by Xiang et al. (1993) in *Ferropenaeus* (*Penaeus*) *chinensis* using chemical and temperature shocks. Deoraj et al. (2005) reported poor viability of tetraploid and polyploid *Litopenaeus vannamei* embryos induced through heat shock, whereas Peeters (1996) reported unsuccessful tetraploid inductions in *Pe-*

*Corresponding author. E-mail: melony.sellars@csiro.au

naeus indicus using chemical shocks. Li et al. (2003) reported successful induction of tetraploid *F. chinensis* embryos, however the larvae were not viable. Notably, all reported tetraploid inductions in shrimp have used temperature or chemical shocks (Xiang et al. 1993, Peeters 1996, Li et al. 2003, Deoraj et al. 2005).

This study aimed to assess the effectiveness of different temperature and chemical shock agents to produce tetraploid *M. japonicus* by preventing the first division in mitosis, which begins at 30 min postspawning at 27°C (Hudinaga 1941). A number of treatments were tested at various times after spawning and for different durations to determine which treatment regimes could be used to produce tetraploid *M. japonicus*.

MATERIALS AND METHODS

Source of Broodstock and Maturation

Wild *M. japonicus* broodstock were captured from coastal waters near Mackay, Queensland, Australia (21°09'S, 149°30'E) by trawling at a depth of approximately 120 m. Broodstock were maintained (25 females: 15 males) in 2,000-L round fiberglass tanks, each fitted with a subsand circulation system (Crococ & Coman 1997). Tanks received 1.6 L min⁻¹ of 10-µm filtered, 34 ppt salinity seawater at 27 ± 2°C and were maintained on a 12 h light:12 h dark cycle. Shrimp were fed commercial *M. japonicus* pellets *ad libitum* once per day and fresh squid (*Loligo spp.*) three times a week during dark hours.

Ovarian development was assessed by shining a torch beam through the dorsal exoskeleton of the females during dark hours (Crococ & Coman 1997). Impregnated females that were ready to spawn (stage IV; Crococ & Kerr 1983) were caught, unilaterally eye-stalk ablated using hot forceps, and transferred to 100-L circular spawning tanks filled to 40 L. Spawning tanks received 0.2 L min⁻¹ of 10-µm filtered, 34 ppt salinity seawater at 27 ± 2°C and were maintained on a 12-h light:12-h dark cycle. Females in spawning tanks were fed one piece (2 cm³) of fresh chopped squid (*Loligo spp.*) daily during light hours.

Spawning Detection and Embryo Collection

Spawning tanks were fitted with an automated spawning detection system (Coman et al. 2003) that accurately detects spawnings of *M. japonicus* within 2 min of spawning. The time of alarm from the automated detection system was taken as time zero and referred to from hereon as time postspawning. For ease of explanation spawned eggs, whether fertilized or unfertilized, will be referred to as embryos from hereon. At 10 min postspawning embryos were siphoned onto a 60-µm screen suspended in a 1-L beaker of seawater. Seawater was allowed to flow out of the beaker, resulting in the concentration of embryos on the screen. Once embryos were concentrated (approx. 60,000–100,000 embryos L⁻¹), the screen was lifted out of the beaker and embryos were rinsed into a beaker containing between 200–800 mL of seawater depending on the experimental design for that spawning. All seawater used for embryo collection, hatching and chemical stock solution preparation was 10-µm filtered and maintained at 27 ± 2°C and 34 ppt salinity.

Induction and Hatching of Collected Embryos

Initial experiments using heat and cold shocks were conducted to assess a range of temperatures for 3 durations (5, 10 and 15 min). Once a suitable temperature shock was established for in-

ducing tetraploidy (based on consistent inductions at the different durations), we further assessed different postspawning treatment times using the 5- and 10-min treatment durations. For the chemical shock experiments a predetermined treatment concentration was chosen based on results of *M. japonicus* triploid induction studies (Norris et al. 2005), which inhibited early embryonic processes. Initial experiments using chemical shock were therefore focused at assessing different postspawning treatment times for variable treatment durations (5–15 min).

Tetraploid inductions were timed to prevent the first division in mitosis. Various shock agents were trialed including heat, cold and chemical shocks. Shocks were applied between 16–28 min postspawning, with durations varying from 5–15 min. Control embryos were included in each experiment or spawning sample and received the same handling stress as their treated siblings. Control and treatment embryos from all spawnings were incubated at 27 ± 2°C with light aeration until hatching. Notably, only spawnings with hatching rates of >40% in the controls were used in this study. Depending on the quantity of eggs spawned and number of available people to complete inductions, in some instances spawnings were divided into two or three spawning samples.

Heat Shock Inductions

Heat shock inductions were completed on 26 spawning samples in total. Heat shocks varied from 32°C to 46°C and were applied from 18–24 min postspawning for a 5, 10 or 15 min duration (Table 1). A similar technique as described by Sellars et al. (2005a) to expose *M. japonicus* embryos to ozone was used to expose embryos to heat shocks. Briefly, concentrated embryos were divided into enough 100-mL aliquots so that there was one for each postspawning treatment time. These aliquots were further divided into enough subaliquots so that there was one for each treatment duration. At the correct postspawning treatment time each subaliquot of embryos was poured through a 60-µm screen, which was placed directly into a seawater bath at the specified heat shock temperature. Each 60-µm screen was removed from the seawater bath after the treatment duration time had lapsed and embryos were rinsed into 200 mL of 27°C seawater. Before, during and after treatment, seawater bath temperature was monitored using a mercury thermometer.

Cold Shock Inductions

Cold shock inductions were completed on 31 samples from different spawnings in total. Cold shocks ranged from 5°C to 23°C and were applied from 16–28 min postspawning for a duration of 5–15 min (Table 2). For samples of spawnings where there was only one postspawning and duration time, treatment was applied by the addition of cold seawater to concentrated embryos. For these spawnings cold shock was stopped by decanting off the cold water once embryos had settled during the shock treatment, followed by the addition of 27°C seawater at the correct time to give the different treatment durations. When a spawning sample was exposed to a cold shock treatment that had different postspawning or duration times, the same procedures as outlined earlier for heat shock inductions were used.

Chemical Shock Inductions

Chemical inductions using a final concentration of 150-µM 6-dimethylaminopurine (6-DMAP) (Sigma) were completed on 14 spawning samples in total. Chemical shock was applied between 18–28 min postspawning for a duration of 5–15 min (Table 3).

6-DMAP was applied to embryos from spawning samples 58–63 using the same procedures outlined by Norris et al. (2005). In brief, 28 mL of a 1-mM stock solution of 6-DMAP was added to 160 mL of seawater containing the embryos. For spawning samples 64–71 a similar technique as described for temperature treatment earlier and by Sellars et al. (2005a) to expose *M. japonicus* embryos to ozone was used to expose embryos to 6-DMAP. Briefly, concentrated embryos were divided into 4 × 100-mL aliquots (one for each of the four postspawning treatment times) to which 50 mL of a fresh 450 µM 6-DMAP stock solution (made up in seawater) was added at the correct postspawning treatment time. Each aliquot was then divided into 3 × 50-mL subaliquots. Subaliquots were poured through a 60-µm screen after the appropriate treatment duration to collect the embryos, which were then transferred to 200 mL of seawater to cease chemical exposure.

Polyploidy Detection and Analysis

Pooled samples of between 5–30 nauplii (less than 30 nauplii were sampled only in instances when less than this hatched) and 50–100 embryos were separately sampled for each spawning from all controls and treatments. In treatments where there were no nauplii hatched, it was only possible to take an unhatched embryo sample. In some instances samples were snap frozen in liquid

nitrogen and stored at -20°C for up to 30 days. If polyploidy analysis could be completed on the day of hatching, nauplii were sampled and taken live to the laboratory and embryos were transported on ice. Snap frozen samples were transported to the laboratory and defrosted on ice. Live nauplii were chilled on ice at the laboratory until they died. Once dead nauplii or embryos had settled, excess seawater was removed, $<200\ \mu\text{L}$ of seawater and sample remained in each tube.

At the laboratory $500\ \mu\text{L}$ of marine phosphate buffered solution (MPBS) ($11.0\ \text{g L}^{-1}\ \text{NaCl}$, $0.2\ \text{g L}^{-1}\ \text{KCl}$, $1.15\ \text{g L}^{-1}\ \text{Na}_2\text{HPO}_4\cdot 2\text{H}_2\text{O}$) propidium iodide (PI) stain (MPBS containing 0.1% Triton X-100, $0.2\ \text{mg mL}^{-1}\ \text{Rnase A}$, $0.02\ \text{mg mL}^{-1}\ \text{PI}$) was added to each sample. Samples were then homogenated individually by aspiration eight times through a 25-G needle pushed firmly against the side of the sample tube. After homogenation $10\ \mu\text{L}$ of a 1:100 dilution of the internal standard, glutaraldehyde fixed, chicken red blood cells (CRBC, Handbook of Flow Cytometry

Methods) was added to each sample. Cell suspensions were screened through $62\text{-}\mu\text{m}$ mesh prior to fluorescent activated cell sorting (FACS) on a Calibur Flow Cytometer (Beckton Dickinson Immunocytometry Systems San Jose, California, USA). A total of 30,000 shrimp cells were analyzed for each sample, however, in some instances only 15,000 shrimp cells were analyzed because there were too few cells in a sample.

Induction rates were calculated for each treatment sample. Initially the proportion of diploid cells in the G2 phase relative to the G1 phase was calculated from a control spawning sample of the same life-history stage. This proportion was used to calculate the number of diploid G2 cells in treatment samples relative to the number of diploid G1 cells in the treatment sample. Once the total number of diploid G2 cells in treatment samples was estimated, the tetraploid G1 peak was calculated by subtracting the diploid G2 estimation from the total number of cells where the tetraploid G1 peak falls (Fig. 1) (within the cell cycle G1 cells are in the growth

Figure 1. Example of a (i) control and (ii) treatment fluorescent activated cell sorting output from *Marsupenaeus japonicus* embryos. The expected size of the diploid G2 peak in (ii) is calculated from dividing the events in the diploid G2 peak in (i) by the diploid G1 peak in (i), and then multiplying this factor by the events in the diploid G1 peak in (ii). When the total number of events of the G2 peak in (ii) was greater than expected (by 5% or more), ModFit analysis was performed to determine the different levels of polyploidy. In this instance the expected diploid G2 peak in (ii) would be $(1470/13531) \times 3226 = 350.47$ events. Because the actual number of events with a DNA content the same as a diploid G2 cell in (ii) is 9911, and we would only expect ~ 350 diploid G2 cells, this output would be analyzed by ModFit to determine the tetraploidy level. CRBC is an internal standard control (chicken red blood cells).

phase, whereas G2 cells have double the normal chromosomal content and are preparing for division). Where the number of cells counted with a DNA content the same as a diploid G2 cell was greater than expected (by 5% or more), the level of polyploidy in that sample was analyzed using ModFit software (Verity Software House, Topsham, Maine, USA). A five percent threshold was chosen based on observed variability among multiple samples taken from the same control groups.

The frequency of producing tetraploid embryos was calculated for the trialed heat shock treatment regimes by dividing the number of spawning samples within a treatment regimen, which had tetraploid embryos by the total number of induction attempts for that treatment regimen.

The effect of heat shock treatment (control, 35°C, 36°C) and duration (5 min, 10 min) on induction rates at 22 min postspawning were analyzed by 2-way ANOVA (PROC GLM; SAS Institute Software, 1999) for spawning samples in which one or more of the treatment combinations resulted in tetraploid embryos. Pairwise comparisons between shock and duration treatments were performed using the least significant difference test.

RESULTS

Heat Shock Inductions

From the initial scoping experiments it was evident that 35°C and 36°C heat shocks were most suitable for inducing tetraploidy. Tetraploid embryos were produced most frequently by a 35°C heat shock applied 22 min postspawning for a 10 min duration (66.67% of the time) (Table 4). Tetraploid induction rates for this 35°C treatment regimen were 8.82, 20.9, 9.9 and 98.1% (ave. \pm S.E.) ($34.4 \pm 21.4\%$) for spawning samples 21, 22 and spawning sample 23 replicate 1 and 2 respectively. The frequency of tetraploid embryo induction was lower for the 36°C heat shock treatments ranging from 33.33% to 45.45% for the 21, 22 and 23 min postspawning treatments at the 5 and 10 min duration times trialed (Table 4). Tetraploid induction rates for the 36°C shock treatments ranged from 13.12% to 61.01%. (ave. $35.0 \pm 5.0\%$). Only one 18

min postspawning induction was applied at 36°C for a 10 min duration which did produce tetraploid embryos, resulting in a 100% tetraploid induction frequency (Table 4).

When treated at 22 min postspawning, tetraploid induction rates of embryos were significantly higher ($P < 0.05$) for the 36°C shock applied for a 5 min duration (ave. $12.81 \pm 5.80\%$) compared with the control (27°C) (ave. $0.00 \pm 0.00\%$) and 35°C (ave. $0.00 \pm 0.00\%$) shock treatments (Table 5). However, when the duration of treatment was increased to 10 min, there was no significant difference between tetraploid induction rates for the 35°C and 36°C shock treatments (ave. 34.43 ± 21.39 and $18.52 \pm 8.53\%$ respectively) and both were significantly higher than controls (27°C) (ave. $0.00 \pm 0.00\%$) (Table 5). Because tetraploid embryos were produced at two of the three duration times trialed for the 36°C shock, compared with only one for the 35°C shock, further experimentation to optimize postspawning treatment times used a 36°C temperature shock.

Although no statistical comparisons were possible as too few spawning samples had tetraploid embryos in the different 36°C shock postspawning treatment times trialed, tetraploid induction rates of embryos were higher on average for the 21, 22 and 23 min postspawning times when the treatment duration was 10 min compared with 5 min (i.e., 61.00%, 18.52% and 53.40% respectively compared with 12.5%, 12.81% and 45.00%) (Table 6). These results suggest that duration had a stronger effect than postspawning time on tetraploid induction.

There were no tetraploid nauplii produced in any of the heat shock treatments trialed. It is also worth noting that all treatment groups for the 39°C and 46°C spawning samples had zero hatch, and FACS outputs of embryos from these treatments were difficult to analyze because the different cell phases could not be discriminated between because of tissue degradation.

Cold Shock Inductions

Only one of the trialed cold shock treatment regimes produced tetraploid embryos. In this treatment, spawning embryos treated at

10 min	0.00 \pm 0.00% ^b (n = 8)	34.43 \pm 21.39% ^a (n = 4)	18.52 \pm 8.53% ^a (n = 8)

5°C for 8 min at 20 min postspawning had a tetraploid induction rate of 15.0%. Nauplii sampled from this same treatment were found to be diploid. All other cold shock inductions failed to induce tetraploidy in any of the embryo and nauplii samples. All spawnings on which cold shocks were applied hatched resulting in all control and treatment nauplii FACS samples containing ~30 nauplii.

6-DMAP Shock Inductions

6-DMAP inductions using a 150- μ M final concentration failed to produce tetraploid *M. japonicus* when applied 18–28 min postspawning, for 5–15 min duration. All embryo and nauplii samples in the control and treatment groups were found to be diploid. All spawnings on which 6-DMAP shocks were applied hatched resulting in all control and treatment nauplii FACS samples containing ~30 nauplii.

DISCUSSION

The results of this study demonstrate that heat and cold shock can prevent the first division in mitosis to produce tetraploid *Marsupenaeus japonicus* embryos. These findings are consistent with those of Xiang et al. (1993) and Li et al. (2003) who successfully inhibited the first division in mitosis in *Ferropenaeus* (*Penaeus*) *chinensis* using temperature shocks to produce tetraploid embryos. To our knowledge there are no other reports of successful tetraploid induction in Penaeid shrimp.

Tetraploid induction rates and frequency of induction of *M. japonicus* embryos were highly variable (0% to 98% and 33.33% to 100% respectively). This finding is similar to other polyploidy induction studies that have attempted to prevent an early embry-

TABLE 6.

Tetraploid induction rates of *Marsupenaeus japonicus* embryos when exposed to a 36°C shock at different postspawning times for a 5 or 10 min duration.

Time Postspawning	Duration	
	5 min	10 min
18 min		32.60% (n = 1)
20 min	0.00 (n = 1)	0.00% (n = 1)
21 min	12.50% (n = 1)	61.00% (n = 1)
22 min	12.81% \pm S.E. 5.80% (n = 8)	18.52% \pm SE 8.53% (n = 8)
23 min	45.00% (n = 1)	53.40% (n = 1)

onic development phase (Xiang et al. 1993, Li et al. 2003, Sellars et al. 2004, Norris et al. 2005). In general, polyploidy induction rates are dependant on three main variables; magnitude of shock (e.g., change in temperature), timing of shock and shock duration. This study showed that increasing temperature by 9°C (from 27°C) between 21–23 min postspawning most consistently produced tetraploid embryos. Shocking the embryos at this time immediately precedes the disappearance of egg-jelly and the first division in mitosis, which begins at 30 min postspawning (Hudinaga 1941).

Shock duration was also shown to significantly affect induction rates, with a 10 min duration resulting in more tetraploid embryos compared with the 5 min duration. Li et al. (2003) also suggested that extended treatment durations may increase tetraploid induction rate. This likely results from shrimp spawning over a period of time, allowing more embryos to reach the embryonic developmental phase at which mitotic division can be prevented when a longer duration of shock is applied. Notably, no tetraploid *M. japonicus* embryos were produced at the longer 15 min duration. This is likely caused by the prolonged duration negatively interfering with the next stages of embryonic development.

Although tetraploid *M. japonicus* embryos were produced, they were nonviable, as determined by FACS analysis of the nauplii. Problems with tetraploid viability have been reported across a range of aquatic species. Li et al. (2003) reported similar problems for *F. chinensis* and were unable to produce viable tetraploid postlarvae by preventing the first division in mitosis. Qui et al. (1997) documented low viability among tetraploid freshwater prawns (*Macrobrachium nipponense*). Poor viability of tetraploids is commonly reported in numerous fish and shellfish species (e.g., Grass carp, *Ctenopharyngodon idella*, Cassani et al. 1990; Black carp, *Mylopharyngodon piceus*, Rothbard et al. 1997; Sydney rock oysters, *Saccostrea commercialis*, Nell et al. 1998; Manila clams, *Ruditapes philippinarum*, Diter & Dufy 1990; Pacific oysters, *Crassostrea gigas*, Guo 1991, cited by Guo & Allen 1994, Guo et al. 1994 and scallops, *Chlamys azumapekten*, Yang et al. 1997).

The genetic, biochemical or biological mechanisms that prevent tetraploid embryos from developing and hatching into viable nauplii remains unknown. In this study, it is unlikely that temperature shock alone was the cause of embryo deaths. This was evidenced by the presence of diploid nauplii hatching within the same temperature shock treatments as the nonviable tetraploids. One explanation proposed by Guo (1992) is that the diploid eggs have insufficient cytoplasmic reserves to develop as a tetraploid. Li et al. (2003) gives no explanation for their nonviable *F. chinensis* tetraploids, however, concluded that tetraploid embryos may have limited viability or ability to hatch.

In this study 6-dimethylaminopurine (6-DMAP) was also assessed as a potential shock agent to prevent the first division in mitosis. However, this treatment was not effective in inducing tetraploidy. Temperature and cytochalasin-B are the only shock agents that have been reported elsewhere to successfully inhibit the first division in mitosis in penaeid shrimp (Xiang et al. 1993, Li et al. 2003).

CONCLUSION

This study shows that the first division in mitosis can be inhibited in *Marsupenaeus japonicus* to produce tetraploid embryos. The most suitable treatment regimen for inducing tetraploidy in *M.*

japonicus, giving frequency and induction rate equal importance, was a 36°C shock administered 23 min postspawning for a 5 or 10 min duration. Notably, none of the tetraploid embryos produced in this study were viable. If sterilization of penaeid shrimp is to be achieved through tetraploidy, future studies will first need to determine why tetraploid embryos are not viable.

ABSTRACT Treatment with hexamethyldisilazane (HMDS) for drying specimens for Scanning Electron Microscopy (SEM) is described for relatively large (>20 mm shell height, SH) individuals of two scallop species, *Placopecten magellanicus* and *Argopecten irradians*. The traditionally used method of critical point drying (CPD) has been applied successfully for smaller specimens (~350 µm up to 15 mm SH); however, occasional rupture of the mantle occurred in these specimens. Furthermore, size limitation of the CPD chamber did not permit preparation of larger individuals. An alternative experimental protocol using HMDS was tested, which successfully preserves the morphology of the bivalve feeding organs, mantle surface and the cilia of the two scallop species with negligible shrinkage and few artifacts. Another benefit of this method is that the number of specimens and sample size is not restricted.

KEY WORDS: bivalve, scanning electron microscopy, method, hexamethyldisilazane (HMDS), ciliation, shrinkage

INTRODUCTION

Scanning electron microscopy (SEM) is a very useful technique to study morphology and surface microstructure of various biological specimens in three dimensions. The drying process is one of the critical steps in specimen preparation for SEM (Laforsch & Tollrian 2000). However, removing water from specimens, particularly hydrated organisms normally causes distortion and collapse because of the effects of surface tension. The two principal methods used to reduce distortion during specimen drying for SEM are critical point drying (CPD) and freeze drying or lyophilization (Maugel et al. 1980, Boyde 1980). Air drying after preparation in organic compounds with low surface tension such as Peldri II (Brown 1990), hexamethyldisilazane (HMDS) (Nation 1983), tetramethylsilane (TMS) (Dey et al. 1989) and dimethoxypropane (DMP) (Muller & Jacks 1975) has also been used.

Critical point drying was first proposed by Anderson (1951) and is one of the techniques more commonly used to dry biological specimens for SEM (Maugel et al. 1980, Boyde 1980). Although we have used CPD for smaller bivalve specimens, namely sea scallop postlarvae, *Placopecten magellanicus*, ~350 µm to 15 mm in shell height (SH), with excellent results (Barré 2001, Veniot et al. 2003), intermittent rupture of the fragile mantle occurs with this method. Additionally, size limitations of the CPD chamber do not permit the use of this method for larger animals (>20 mm). In this study larger bivalve specimens were dried using a HMDS protocol that minimizes shrinkage and preserves the cilia and fragile mantle of the organisms.

The principle of the technique relies on replacement of an ethanol dehydration medium with HMDS, which is subsequently evaporated. HMDS has a lower surface tension than water and is believed to provide structural support by cross-linking proteins (Nation 1983, Braet et al. 1997). The suitability of HMDS for drying biological specimens has been shown on insects (Nation 1983, Heraty & Hawks 1998), aquatic organisms (shrimp eggs, daphnids, gastrotichs) (Moraes & Bouzon 1995, Hochberg & Litvaitis 2000, Laforsch & Tollrian 2000), organic microstructures on bivalve shells (Schöne & Bentley 2002), pollen (Chissoc et al. 1994), dinoflagellates (Botes et al. 2002), anaerobic biofilms and

granular sludge (Aratjo et al. 2003), and cultured rat hepatic endothelial cells (Braet et al. 1997). Most of the studies have examined insects and small specimens, typically <10 mm.

Here we use SEM to show the morphology of feeding organs (gill, foot, labial palps and arborescent lips), and ultrastructural characteristics such as ciliation in large specimens of two bivalve species, the sea scallop, *Placopecten magellanicus*, and bay scallop, *Argopecten irradians*. An experimental protocol has been used that successfully preserves the organ morphology and cilia of large bivalves (>20 mm SH). Our observations will contribute to understanding the feeding mechanisms of these animals during development.

MATERIALS AND METHODS

Large specimens (>20 mm SH) of the two scallop species *P. magellanicus* and *A. irradians* were collected for examination by SEM. Scallops were sampled from field sites and reared at the Institute for Marine Biosciences' Marine Research Station (MRS), Ketch Harbour, Nova Scotia, Canada.

Animals were refrigerated at 4°C for one hour prior to anesthetization to decrease their metabolism. A gradual addition of MS-222 (Tricaine Methanesulfonate) and KCl (5% potassium chloride) allowed for both muscle tissue relaxation (gaping valves and non contracted tissues) and limitation of mucus production. During this process, sample vials (250-mL glass jars) were not agitated and kept at 4°C. Scallops were fixed in 1G4F (1% glutaraldehyde, 4% formaldehyde, in 0.2M PO₄, pH = 7.5) for a minimum of 48 h at 4°C.

During subsequent processing, samples were gently agitated in a fume hood at room temperature. Specimens were rinsed twice for one hour in a 0.2 M PO₄ buffer solution (pH = 7.2) and dehydrated in ascending ethanol washes (twice at each concentration for one hour in 50, 70, 80, 95 and finally 100% ethanol). Transitional steps of 100% ethanol (30 min, 30 min, 1h) and then HMDS: ethanol (1:1) (30 min, 30 min, 1 h) were followed by two baths (1 h each) of 100% HMDS. Finally the jars were placed in a dessicator with silica gel with just enough HMDS to cover the specimens.

The gross morphology of the scallops was observed using a Wild M400 Photomakroskop and a Nikon Coolpix 4500 digital

Plate 1: Results of HMDS treatment on the organization of the organs (binocular microscope observations) in the sea scallop, *Placopecten magellanicus* (Fig. 1, 2, 3) and on microstructure as examined by Scanning Electron Microscopy in the bay scallop, *Argopecten irradians* (Fig. 4, 5, 6). (See Veniot et al. 2003 for a description of the morphology and organization of feeding organs during ontogeny in *P. magellanicus*). camera. For SEM observation, specimens were mounted on aluminum stubs with double-sided carbon tape and the right valve was removed. Samples were then sputter-coated with gold-palladium (Model SC7620 Polaron) and examined using a Hitachi Model S-3000N SEM at 20kV.

RESULTS AND DISCUSSION

Specimens of *P. magellanicus* dried after HMDS treatment showed well-preserved surfaces with negligible shrinkage of the tissues and few artifacts (Plate 1, Fig. 1, 2, 3). The extended foot

and intact gill (Plate 1) were relaxed and showed good preservation. The fragile mantle surface was well preserved with no shrinkage or tears (Plate 1, Fig. 2). The radial muscles were visible and well preserved. Feeding organs (lips, labial palps and foot) were intact and the arborescent lips (described and drawn by Beninger et al. 1990) were photographically recorded for the first time (Plate 1, Fig. 3). The labial palps–gill connection (type III according to Satsek 1963) was also shown (Plate 1, Fig. 3).

HMDS drying also provided excellent results in the preservation of microstructural characteristics such as ciliation of scallop feeding organs, as illustrated in the gills and labial palps of *A. irradians* specimens (Plate 1, Fig. 4, 5, 6). There were no visible distortions of the cilia as shown on the frontal cilia of the gill (Plate 1, Fig. 4) or the cilia of the ridges of labial palps (Plate 1, Fig. 6). Tufts of cilia on dorsal expansions of the gill were not shrunk and cilia at the base of the tufts were not clumped (Plate 1, Fig. 5).

HMDS treatment has been used for a number of different specimen types, generally less than 10 mm and was shown to require less time and expertise than critical point drying (Hochberg & Litvaitis 2000, Laforsch & Tollrian 2000, Schöne & Bentley 2002). The method is used in this study to prepare large specimens of scallops *P. magellanicus* and *A. irradians* for observation of feeding organs and cilia development. Oshel (1997) showed that HMDS use was effective for preparing soft and highly hydrated specimens. Also, HMDS drying preserved excellent surface details in insect tissues (Nation 1983, Heraty & Hawks 1998) and hepatic endothelial cells (Braet et al. 1997). This work shows that large specimens (20–30 mm SH) of marine bivalves can be preserved

and dried for SEM without major distortion or collapse and microstructural details are retained.

Intermittently, when using the CPD method for smaller specimens (scallop <15 mm SH) the mantle surface was partially or totally destroyed. All of the samples in this study consistently had intact mantle surfaces. Another difficulty encountered in the preparation of ciliated epithelia for SEM is the tendency for the cilia to stick together and for foreign particles to remain on the cilia. The ciliated surfaces of the feeding organs in *A. irradians* dried using HMDS showed nonclumped, relatively particle-free tufts (Plate 1, Fig. 4, 5, 6). Drying from HMDS seemed to prevent shrinkage, whereas the CPD method appeared to have caused some distortions (Barré 2001). Another advantage of the HMDS method is that the number of specimens and sample size are not restricted. Thus we conclude that the quality of the results obtained and ease of use of the HMDS drying process make it preferable to the CPD method for processing large bivalve specimens.

ACKNOWLEDGMENTS

The authors thank Steve McKenna and Scott MacQuarrie of the National Research Council, Institute for Marine Biosciences for helping rear the animals at MRS; Cindy Leggiadro of the Microscopy Facility for her expertise; Anne Veniot, University of Moncton, New Brunswick, Canada, for assistance in training and C. Barré in SEM methodology, during early stages of her research. This research was supported by an NCE AquaNet grant to V. M. Bricelj (IMB) and C. Parrish and R. Thompson from the Ocean Sciences Centre, Memorial University of Newfoundland.

A NEW *IN SITU* METHOD FOR MEASURING SESTON UPTAKE BY SUSPENSION-FEEDING BIVALVE MOLLUSCS

RAYMOND E. GRIZZLE,¹* JENNIFER K. GREENE,¹ MARK W. LUCKENBACH² AND LOREN D. COEN³

¹Jackson Estuarine Laboratory and Department of Zoology, University of New Hampshire, Durham, New Hampshire 03824; ²Virginia Institute of Marine Science, College of William and Mary, Eastern Shore Laboratory, Gloucester Point, Virginia 23062; ³Marine Resources Research Institute, South Carolina Department of Natural Resources, Charleston, South Carolina 29412

ABSTRACT The most commonly used methods for measuring the amount of seston removed from the water column (uptake) by populations of suspension-feeding bivalve molluscs involve taking discrete water samples followed by laboratory analyses. Here we describe a new method based on *in situ* fluorometry that provides rapid measurement of seston removal rates. The new system is comprised of two identical units, each consisting of an *in situ* fluorometer, data logger and peristaltic pump with plastic tube attached to a deployment device. The deployment device allows precise placement of the fluorometer probe and intake end of the plastic tube so that *in situ* fluorescence (chlorophyll *a*) can be measured and water can be sampled for seston analyses in the laboratory from the same height. The typical setup involves placing one unit upstream and the other downstream of the study area and sampling the water at periodic intervals. Changes in seston concentration are revealed in the field by the fluorometers, and the sampled water can be analyzed in the laboratory for various seston parameters. Comparisons of the *in situ* data with data from laboratory analyses of pumped water samples were made for three species at four study sites: the eastern oyster (*Crassostrea virginica*), hard clam (*Mercenaria mercenaria*), and blue mussel (*Mytilus edulis*). Comparisons of measured upstream versus downstream seston concentrations indicated significant (*t*-tests, $P < 0.05$) differences (uptake) for six of eight trials based on *in situ* fluorometry, but only marginally significant ($P < 0.10$) differences at two of the four trials using laboratory chlorophyll *a* measurements. These data demonstrate that compared with sampling methods requiring laboratory analyses, the new *in situ* method provides much more rapid quantitative assessments and may provide more accurate estimates.

KEY WORDS: bivalve, fluorometry, seston uptake, suspension-feeding, *Crassostrea*, *Mercenaria*, *Mytilus*

INTRODUCTION

Empirical and theoretical research demonstrates that populations of suspension-feeding bivalve molluscs can remove substantial amounts of suspended particulates (seston) from the overlying water column by their feeding activities (Ulanowicz & Tuttle 1992, Dame 1996, Newell et al. 2005, Haamer & Rodhe 2000, Cressman et al. 2003, Nelson et al. 2004). This has important implications for shellfish aquaculture and more recently for water quality management associated with shellfish restoration projects (Luckenbach et al. 1999, 2005, Thayer et al. 2005). Field studies on seston uptake typically involve laboratory analysis of discrete water samples obtained manually or by pumps (Dame & Libes 1993, Newell & Shumway 1993, Cressman et al. 2003, Nelson et al. 2004). This approach is effective and it allows the measurement of multiple water parameters. However, there is a need to develop *in situ* approaches that have the potential to greatly increase the spatial and temporal resolution of measurements of the feeding/seston uptake process.

A major impetus for development of the new method is the need for quantitative success metrics for constructed shellfish (mainly oysters) reefs that are part of ongoing restoration programs in many areas. These projects often emphasize the ecological functions of oysters, instead of or at least in addition to, their historical role as a commercial resource (Luckenbach et al. 1999, 2005, Brumbaugh et al. 2000, Coen & Luckenbach 2000). One of the major ecological functions of oyster reefs is their potential influence on water quality because of their filtration capacity (Dame 1996, Dame et al. 2001, French McCay 2003, Peterson et al.

2003). Field studies, however, typically have not demonstrated measurable seston removal by natural (Dame & Libes 1993, Wilson-Ormond et al. 1997) or restored (Nelson et al. 2004) oyster reefs. Cressman et al. (2003) is the only study we are aware of that measured substantial (up to 25%) removal of seston by small intertidal reefs. Hence, there is a need to critically assess this often-cited reason for restoring shellfish reefs (Coen & Luckenbach 2000, Luckenbach et al. 2005). How much of an impact on water quality should be expected from restored shellfish reefs?

Previous research has used *in situ* fluorometry to assess food availability to cultured bivalves (Grant & Bacher 1998) and phytoplankton biomass as part of broader ecological studies (Gregor et al. 2005). However, we are not aware of previous attempts to use *in situ* fluorometry to measure seston uptake by benthic organisms in the field. Here we describe a novel method for directly measuring uptake rates, and the results of field trials involving three bivalve species that compare measurements using the new *in situ* method with laboratory analysis of pumped water samples.

DESCRIPTION OF *IN SITU* FLUOROMETRY APPARATUS

Each apparatus consists of a fluorometer (Seapoint Sensors Model SCF) with multimeter/datalogger (Extech Model 383.274), and peristaltic pump (Masterflex Model 7533) with 1-cm ID plastic tube attached to a custom-made deployment device (Fig. 1A, B, C). The fluorometer probe is placed within a 5-cm ID PVC pipe that is attached to the bottom plate. The probe and light shield are held in position by a hose clamp on the outside of the PVC pipe; loosening of the clamp allows the light shade and probe to be moved up and down on the pipe and secured at any height above the bottom plate. The bottom plate is designed to rest on the bottom so the fluorometer probe remains at the same height

*Corresponding author. E-mail: ray.grizzle@unh.edu

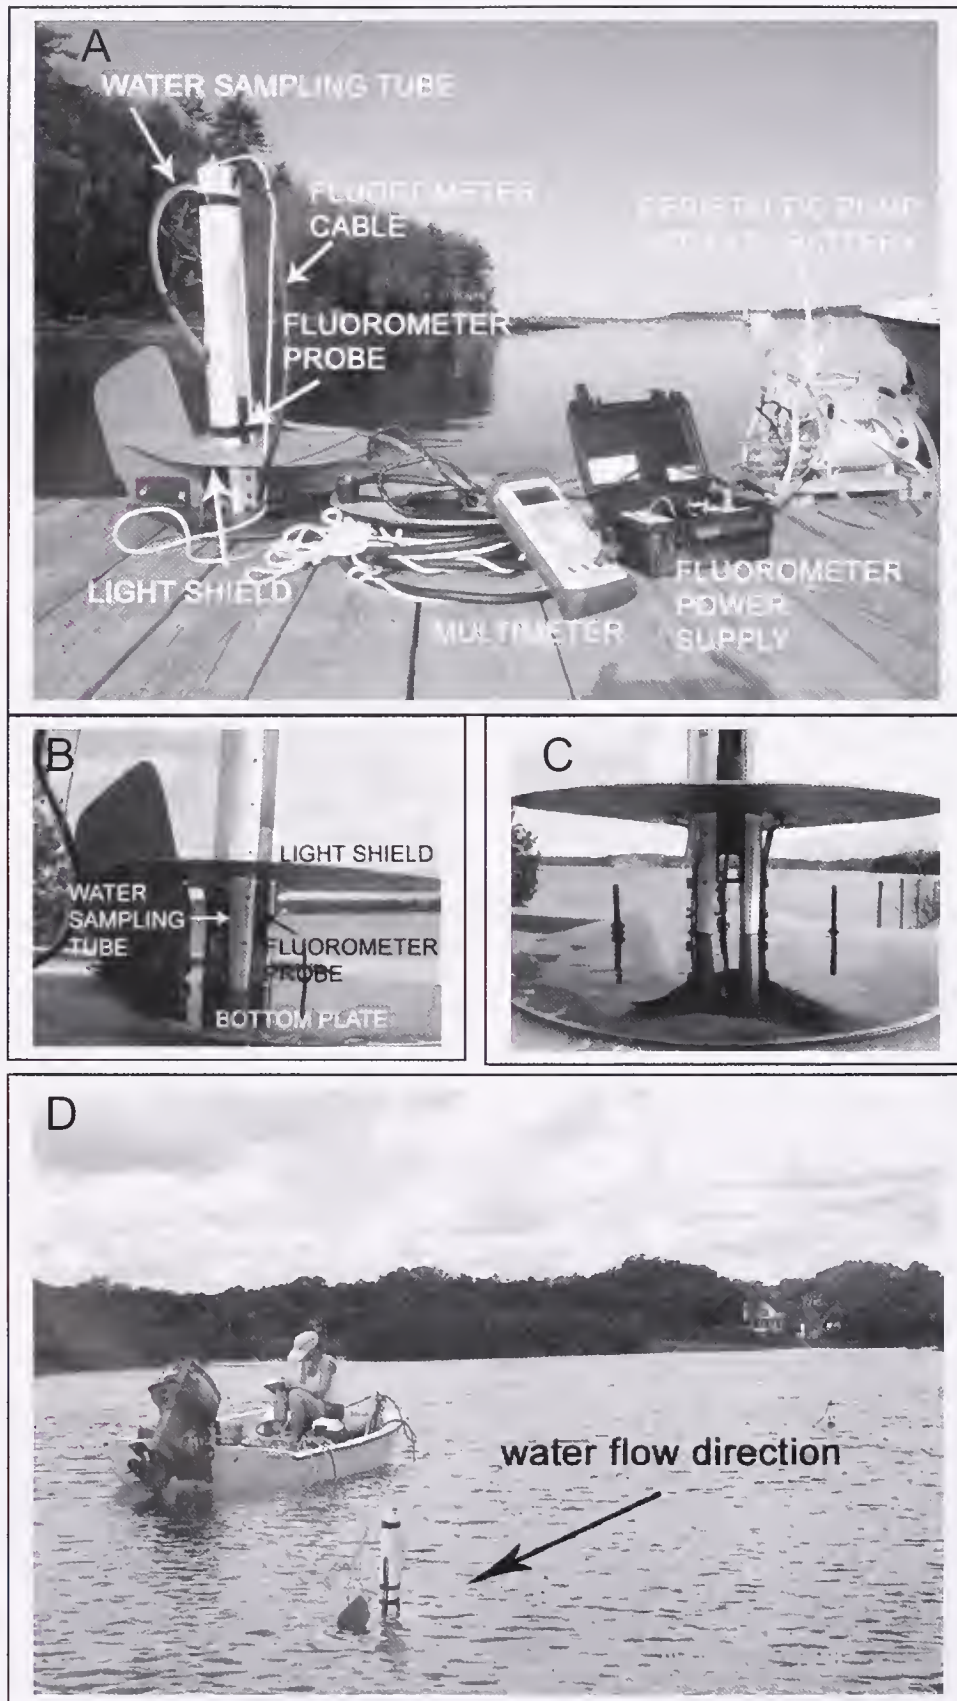

Figure 1. New *in situ* fluorometer and water sampling apparatus. (A) Complete apparatus (one of two identical units); (B) close up oblique view of fluorometer probe in deployment device; (C) close up face-on view; (D) deployment of two identical units over intertidal oyster reef in Florida.

throughout the measurement period, but the entire apparatus can be suspended at any height and moved up and down in the water column as needed. A tail fin attached to the bottom plate orients the probe so that water flows directly through the sensing chamber as it is lowered to the bottom (Fig. 1C). The bottom plate is constructed of 2-mm thick stainless steel sheet material and provides sufficient weight to hold the apparatus in position under most flow conditions. The fluorometer probe and the end of the water intake tube are placed at the same height so that comparisons can be made between *in situ* fluorescence (chlorophyll *a*) and laboratory analysis of pumped water. Total cost of each unit is about \$5,000 (2006 US\$).

The typical setup involves placing one apparatus upstream and another downstream of the study population and sampling the water at periodic intervals (Fig. 1D). To be sure the downstream apparatus is exposed to the same water mass as the upstream apparatus, a floating object is released periodically from the upstream position to show the ambient water flow path across the reef. Adjustments in location of either device, including raising the apparatus to allow the tail fin to reorient the probe with respect to water flow direction, can be made as needed. Changes in seston concentration caused by bivalve feeding ("seston uptake") are revealed immediately by differences in the two fluorometer readings (upstream vs. downstream), and the sampled water can be analyzed for various parameters to verify the fluorometry and provide additional data on changes in seston characteristics.

MATERIALS AND METHODS

Populations of bivalve molluscs were studied at sites in New Hampshire (a blue mussel, *Mytilus edulis*, reef), Virginia (hard clam, *Mercenaria mercenaria*, beds at an aquaculture farm), South Carolina (a restored eastern oyster, *Crassostrea virginica*, reef), and midAtlantic Florida (several natural eastern oyster reefs). Table 1 summarizes the environmental characteristics of the study sites, and the measured seston uptake rates. Sites were chosen because they met two criteria: (1) water less than ~1.5 m deep and (2) water flow constrained laterally, or width-to-length ratio sufficient to minimize lateral transport across the width of the sampled area. Meeting these criteria would likely result in environmental conditions (e.g., well mixed water column) that would allow sampling at one height to be representative of the entire flow field.

The general protocol for field studies consisted of making repeated measurements of environmental conditions and changes in seston concentration upstream and downstream of each population of bivalves based on *in situ* fluorometry and laboratory analysis of pumped water samples (Table 1; Fig. 1C). Each of the fluorometer probes and water intake tubes were set at 5–10 cm above the bottom (either the top of the reef for mussels and oysters or the sediment surface for clams). A set of measurements (each consisting of 10–20 fluorometry readings recorded at 10-s intervals) was made at 10-min intervals for the duration of each deployment at each site (except for the South Carolina study, which consisted of single readings recorded at 5–15-min intervals). The peristaltic pumps required about 5 min to obtain each sample. Readings from the two fluorometers also were compared side-by-side at the beginning of each deployment and again after the last set of readings was taken to be sure they gave similar readings.

Pumped water samples were stored in the dark on ice and returned to the laboratory for filtration (Whatman GF/C or Gelman GF/F filters) within 6 h of collection; the filters were further pro-

TABLE 1.
Summary of environmental characteristics, bivalve population data, and other information for all study sites.

cessed immediately in most cases, or frozen until processed. The New Hampshire, Florida and Virginia samples were analyzed spectrophotometrically using acetone extraction and standard techniques (APHA 1992). The South Carolina samples were analyzed fluorometrically following a modified EPA Method 445.0 procedure (Arar 1997, Rev. 1.2).

Bivalve densities were determined at most sites by sampling 5 to 10 of 0.16 m² quadrats, counting and measuring shell length or height of all live bivalves collected to the nearest mm using calipers. For the South Carolina oyster reef, data on bivalve size and density available from previous samples taken at that site were used. Flow length was the distance between the two fluorometers. Water depth was measured at 10-min intervals using a marked rod. Water flow speed was measured at the same height as the fluorometer probes were placed (5–10 cm above the bottom) with a Marsh-McBirney Model 201 electromagnetic current meter, with 10–20 replicate speeds recorded at 10-s intervals every 10 min for the duration of the measurement period. Near-surface water speed and flow direction were also estimated by releasing an orange at the upstream site and recording travel time to the downstream site. This provided a measurement of near-surface water flow speed to compare with the near-bottom measurements and insured that the sampling units were placed properly.

Data analysis consisted of comparisons of chlorophyll *a* concentrations, based on field data (*in situ* fluorometry) with laboratory analysis of pumped water samples. Data were analyzed graphically (scatterplots), and statistically (*t*-tests, regression and correlation) using SYSTAT version 10 (2000) software. For the *in situ* fluorometry data only, the *t*-tests were done using the means of the mean values for each 10-min observation period.

RESULTS AND DISCUSSION

A total of eight trials of paired upstream versus downstream *in situ* fluorometry measurements were taken at the four study areas; pumped water samples were taken for laboratory chlorophyll *a* analysis during four of the eight trials (Table 1). *T*-tests indicated significant differences between mean upstream and downstream fluorometry readings for six of the eight trials (Fig. 2), but only marginally significant ($P < 0.10$) differences at two of the four trials for laboratory measurements (Fig. 3). Both approaches, however, showed instances of seston uptake rates exceeding 25%.

A scatterplot of the full dataset comparing each *in situ* fluorometry reading with its corresponding laboratory chlorophyll measurement showed two distinct groupings (Fig. 4). Overall, this assessment indicated that the two measurement techniques yield comparable data, but their relationship is not simple.

Using *In situ* Fluorometry to Provide Rapid Measurement of Seston Uptake

As already noted, field studies on seston uptake typically have involved laboratory analysis of discrete water samples obtained manually or by pumps using various sampling protocols (e.g., Dame & Libes 1993, Judge et al. 1993, Newell & Shumway 1993, Cressman et al. 2003, Nelson et al. 2004). We obtained pumped water samples for laboratory analysis as means of "ground truthing" the *in situ* fluorometry data because in the long-term our goal is to rely as much as possible on the latter. Most applications of *in situ* fluorometry to date have been in the area of water quality monitoring (e.g., Gregor et al. 2005), in some cases (e.g., Grant & Bacher 1998) related to bivalve aquaculture. Our application es-

entially represents an ecological extension of the method, but it required some important modifications to off-the-shelf fluorometers. Ambient sunlight can strongly interfere with the sensor, so a large aluminum plate was added to shade the probe (Fig. 1). It was also necessary to construct a deployment apparatus that allowed precise placement of the probe vertically, and it automatically oriented the probe so the predominant water flow was directly through the sensor chamber. These modifications have resulted in an apparatus that is simple to deploy and appears to consistently yield reliable data.

In situ fluorometry could become a fast, effective and nondestructive approach to quantifying the impacts of shellfish populations on seston removal but it needs further development, including more comparisons with laboratory analysis of pumped water samples. One of the issues that will need to be settled for some applications concerns the relationship between the *in situ* fluorometry data and laboratory-determined chlorophyll *a* concentrations. Our data from four different areas showed two distinct groups, with substantial disparity between the two in the relationship between fluorescence and chlorophyll *a* concentrations determined by wet chemistry techniques (Fig. 4). Grant and Bacher (1998) also reported substantial disparities between the two approaches. Gregor et al. (2005) noted that differences between *in situ* fluorometric methods and laboratory methods should be expected when different analytical techniques (e.g., ethanol vs. acetone extraction) are compared and phytoplankton taxonomic composition varies. For our data, the pumped water samples were a composite taken over about 5 min, as compared with multiple fluorometry reading taken over about 2 min (see Methods section). Hence, although both types of samples were taken at approximately the same time, some of the differences (Fig. 4) could represent actual temporal variability in seston concentrations.

Another potential limitation of *in situ* fluorometry is that it does not provide data on components of the seston other than phytoplankton that can be important food items for bivalves. However, if chlorophyll *a* data alone are sufficient then *in situ* fluorometry represents a much more effective approach compared with analysis of pumped water samples because it provides rapid results, and if fluorometers are deployed at multiple heights in the water column, spatial variations in seston removal that are related to hydrodynamical factors can be assessed. For example, a fully mixed water column is not necessary for estimating uptake rates.

Seston Uptake by Oyster Reefs

As discussed earlier, the need to estimate the potential impact of constructed or restored oyster reefs on water quality has driven the development of the *in situ* fluorometers. The potential for bivalve shellfish to control phytoplankton populations in coastal areas such as San Francisco Bay was proposed over 20 y ago (Cloern 1982, Officer et al. 1982). Subsequent studies in the Bay documented a variety of ecological effects, including seston depletion, attributable to dense infaunal bivalve populations (e.g., Alpine & Cloern 1992). In a widely cited paper, Newell (1988) hypothesized that the historical depletion of oyster populations in Chesapeake Bay has been a major factor in water quality degradations and other ecological changes in the Bay (also see Heck 1987). Subsequent studies support this notion (Ulanowicz & Tuttle 1992, Newell 2004). Similar water quality impacts in some areas of the Great Lakes by the invasive zebra mussel have also been documented (Budd et al. 2001, Ackerman et al. 2001). Recent research in mesocosms has further characterized the role that sus-

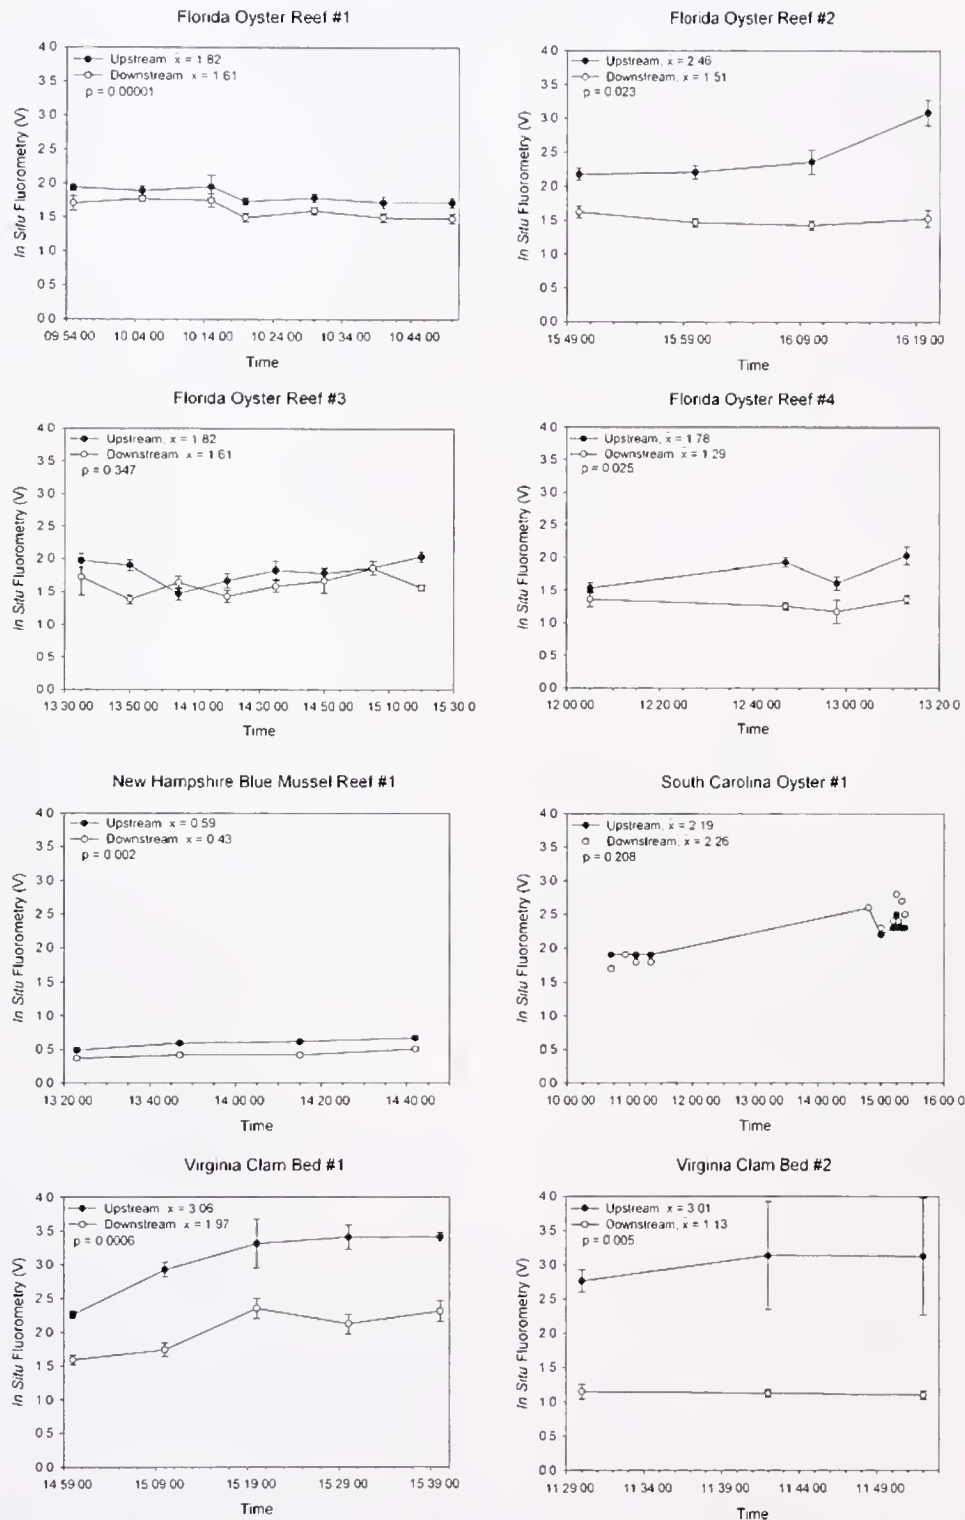

Figure 2. Upstream and downstream *in situ* fluorometry measurements for all study sites. *P* values from *t*-tests; error bars show 1 SD.

pension-feeding bivalves can play in controlling phytoplankton populations (Cerrato et al. 2004, Porter et al. 2004). It seems reasonable to expect measurable water quality effects from restored oyster reefs, but empirical studies of the effects are needed.

Several field studies involving bivalves such as clams, mussels and other taxa have demonstrated substantial seston uptake and in

some cases longer-term water quality changes caused by bivalve feeding and filtration (e.g., Alpine & Cloern 1992, Haamer 1996, Coen et al. 2000, Haamer & Rodhe 2000, Ackerman et al. 2001; see reviews by Dame 1996 and Dame et al. 2001). Field studies on oysters, however, typically have shown no measurable uptake or very little (Dame & Libes 1993, Wilson-Ormond et al. 1997, Nel-

Figure 3. Upstream and downstream laboratory measurements of chlorophyll *a* concentrations from pumped water samples for all study sites. *P* values from *t*-tests.

son et al. 2004); Cressman et al. (2003) is the only field demonstration of substantial seston removal (up to 25% decreases in chlorophyll *a*) we are aware of for oyster reefs. In the present study, maximum measured seston uptake rates for the three bivalve species ranged from 27.8% for *Mytilus*, 37.4% for *Crassostrea*, to 62.3% for *Mercenaria*. The differences in rates mainly reflected differences in bivalve size and densities relative to water flow and

water depth (Table 1). Hence, it seems reasonable to conclude that field studies on oysters should consistently yield quantitative measures of seston depletion if they are properly scaled. In any case, our new *in situ* device would allow rapid assessments for future studies on restored and natural oyster reefs.

ACKNOWLEDGMENTS

The authors thank Jamie Adams, Nancy Hadley, Josh Luckenbach, Andrew Hollis, Michael Hodges and M. Bolton-Warberg for assistance in the field and/or laboratory; Al Curry for laboratory analysis of water samples; Mark Capone for assistance with data processing; Linda Walters for kindly allowing us to use the Feller House as a base of operations for the Florida oyster reef studies in the Canaveral National Seashore, John Stiner assisted in coordinating the studies there and Michael Pierson for allowing access to the clam beds at Cherrystone Aquafarms. Funding was provided by the Cooperative Institute for Coastal and Estuarine Environmental Technology and Jackson Estuarine Laboratory at the University of New Hampshire, South Carolina Sea Grant and the South Carolina Department of Marine Resources and the Eastern Shore Laboratory of the Virginia Institute of Marine Sciences. The South Carolina portion of this research was funded by Grants from NOAA's South Carolina Sea Grant Consortium (#NA16RG2250, #NA03NMF4630272), Fish America (FAF3036), and the South Carolina Department of Natural Resources through its Marine Resources Research Institute. This is Contribution #434 from the University of New Hampshire, Jackson Estuarine Laboratory Contribution Series; #585 from the Marine Resources Research Institute, South Carolina Department of Natural Resources; and #2750 from the Virginia Institute of Marine Science. The South Carolina work was supported by the ACE Basin NERR.

OVERVIEW, 26th MILFORD AQUACULTURE SEMINAR.

Walter J. Blogoslawski, U.S. Department of Commerce, National Oceanic & Atmospheric Administration, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, 212 Rogers Ave., Milford, CT 06460, USA

In early 1975, fifteen persons gathered at the First Milford Aquaculture Seminar to discuss the role of industry, research, and government in managing the complex interactions of society's needs and the environment to shape the fledgling United States efforts in aquaculture. Twenty-six years later, one hundred and fifty-five attendees of the joint 26th Milford Aquaculture Seminar and the Juvenile Oyster Disease Session met from February 27–March 1, 2006 in Meriden, Connecticut to examine how well this important and difficult charge has been addressed and to discuss future challenges and opportunities in this evolving field.

This annual meeting is a unique blend of industry, academics, government, and research that results in sessions that are informative and in observations that prove invaluable because of the many ways an issue is examined depending upon the disciplines of the persons involved in the discussion. This collaborative approach brings the best of all worlds to topics as varied as disease, regulation, genetics and nutrition. Input is received from those who work primarily in a laboratory or a classroom and from those who spend their time in the hands-on process of animal husbandry, each receiving valuable insights from the other's experience. This easy partnering of experience and formal research helped the meeting to achieve the goal of sharing knowledge to achieve excellence in aquaculture practices consonant with a keen awareness of our stewardship of the environment.

The 26th Milford Aquaculture Seminar attracted 17 posters and 52 oral presentations on subjects covering disease, genetics, animal husbandry, shellfish restoration, aquaculture legislation, nutrition, technology, and an update on the NOAA Aquaculture Program. A concurrent Juvenile Oyster Disease (JOD) session explored industry cases, transmission, and treatment and resistance to JOD.

Participants came from thirteen US states and from the countries of Pakistan, Korea, France and Canada. Nineteen universities sent professors or students and two Connecticut magnet schools and one Massachusetts High School participated. Four universities sent NOAA-Sea Grant cooperative extension agents. Sixteen aquaculture companies attended as did several independent shellfish growers. Many marine laboratories participated including federal US laboratories from Milford, CT, Woods Hole MA, USGS Kearneysville, WV, NOS Hollings Marine Lab, Charleston, SC, USDA-NRAC, College Park and NOS Oxford, MD. Federal program information was brought to the meeting from the NOAA Aquaculture Program, Silver Springs, MD and NOAA Chesapeake Bay Office, Annapolis, MD. State institutes and municipal departments attending included the University of Maryland's Center for Marine Biotechnology, the Rhode Island Department of Environmental Management, New Hampshire Fish and Game, Oak Bluff's

and Edgerton, MA Shellfish Departments, the State of Connecticut Aquaculture Division, and the Connecticut Department of Environmental Protection.

The diversity of the participants, coupled with the high caliber of the presentations in an atmosphere that encouraged positive formal and informal discussion, ensured a dynamic and worthwhile meeting for all. Surely, the 26th Milford Aquaculture Seminar and the joint Juvenile Oyster Disease session addressed the need for such an information exchange and have remained faithful to the original intent of the First Milford Aquaculture Seminar—to make available the latest research and industry experience so that aquaculture might be conducted in a responsible and productive manner.

PROTOCOL VALIDATION FOR THE USE OF THE FLUORESCENT ENZYME PROBE ELF97 TO ASSESS PHOSPHATE NUTRIENT STATUS OF INDIVIDUAL PHYTOPLANKTON CELLS. Jennifer H. Alix,¹ Shannon L. Meseck,¹ Sebastian Saliou,² J. Evan Ward,³ and Gary H. Wikfors.¹ ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Pâtisseries Gourmandes SA, 22602 Loudeac Cedex, France; ³Department of Marine Sciences, UCONN, Groton, CT 06430

Methods used in the past to assess the nutrient status of phytoplankton populations have been indirect, inferred from changes in growth correlated with external, dissolved nutrient concentrations. A much more direct approach is to measure enzymes induced by nutrient uptake or deficiency within the phytoplankton cells themselves, but early methods required extraction of enzymes from bulk samples comprised of many cells, thus limiting resolution to the entire phytoplankton community in field samples or an average of all cells in a culture. Recently, fluorescent probes that bind uniquely to specific enzymes within cells have been developed, mainly for biomedical applications. We currently are testing cross-field application of several of these probes for use with phytoplankton cells. As phosphate status of phytoplankton is an important consideration in both natural and culture assessments of phytoplankton, we have focused on a probe, ELF97, for the phosphate reductase enzyme induced under conditions of phosphate deficiency. The general approach was to induce phosphate deficiency in phytoplankton cultures and compare fluorescence intensities of P-deficient and P-sufficient cultures; a significant difference indicates the ability to distinguish the two nutrient-status conditions.

Preliminary experiments were done to modify and optimize the details of sample handling and probe concentration from medical samples to phytoplankton. Then, 15 strains representing 10 different classes of algae were inoculated into artificial seawater medium, ASP₂, with normal or zero phosphate enrichments. After two serial subcultures, dissolved phosphate concentrations and

particulate phosphorus were determined to ascertain the availability of this nutrient in the cultures. Probe fluorescence within cells was observed qualitatively by epifluorescence microscopy, and fluorescence intensity of individual cells was determined by flow-cytometry. In all algal species we were able to starve for phosphate, there was a significant increase in cellular mean probe fluorescence from P-sufficient to P-deficient nutrient status, indicating that this probe is widely-applicable for determining phosphate status of many phytoplankton taxa. Probes to test phytoplankton nitrate reductase, lipid content, viability, and apoptosis will be tested in the future

VARIATIONS IN THE TIMING OF SPAWNING IN THE POPULATION OF WILD BAY SCALLOPS, *ARGOPECTEN IRRADIANS*, IN NANTUCKET HARBOR. Peter B. Boyce, Robert S. Kennedy, Valerie A. Hall and W. Forrest Kennedy, Maria Mitchell Association, 4 Vestal Street, Nantucket, MA 02554, USA

During the summer and early fall of 2004 and 2005 we measured the timing of the spawning and subsequent set of the bay scallop *Argopecten irradians* population in Nantucket Harbor using the wet Gonad Index (GI) of samples collected at 2 to 3 week intervals and spat collecting bags set out at 3–6 week intervals. After eight weeks, or longer, the bags were collected and the number of small seed scallops in each bag were counted and measured if large enough to do so.

In 2004, the spawn began as a dribble in July with the main event occurring from mid-August to early September. Spat lines set early in the summer contained no more than a handful of seed, while a spat line deployed on 14 September 2004 and examined on 17 November averaged 350 small seed per bag with a mean size of 3.3 ± 1.2 mm. The size distribution of the overwintering population was derived from a composite of all spat bag scallops plus samples obtained during 25 m² bottom transects. The predominant component was a subpopulation of small seed with a mean shell height of 11 ± 3 mm. In addition there were a small number of larger size seed. No seed scallops with a shell height >40 mm were found.

The 2005 spat bag data indicate the main spawning event occurred in July with a significant dribble spawn occurring throughout August and into September, virtually a mirror image of the 2004 behavior. Spat lines with five bags set out at two places in the harbor on 24 July 2005 and checked on 28 September 2005 yielded an average of $2,300 \pm 700$ and $2,100 \pm 300$ seed per spat bag. Most of the overwintering population in 2005–2006 apparently originated from this spawning event. The amount of seed is larger than in the previous years and the individuals are also larger, with a mean shell height of 52 ± 4 mm. This was 41 mm larger than the 2004 overwintering seed, and 10 mm larger than in 2003 when the mean shell height was 42 ± 4 mm.

The GI was determined for samples of randomly selected adult

scallops during the 2004 and 2005 growing season. In 2004, the Gonad Index remained above 20 (indicating a full gonad) through the end of July before dropping to 7 (empty gonad) by September 15. In 2005 the onset of the GI decline was less well defined, beginning approximately June 19 and reaching low values before August 11.

Although the small seed from 2004 did survive the winter, it did not reach adult size in 2005. More than 98 percent of the 2005 population that we sampled consisted of adult scallops that had survived a second winter, exhibiting two annual growth rings, one at 40mm and the second at 50–65mm. The GI data for 2005 comes almost exclusively from these third season scallops.

IN VITRO INVESTIGATIONS OF QUAHOG PARASITE UNKNOWN (QPX). Deenie M. Buggé, Mickael Perrigault and Bassem Allam, Marine Sciences Research Center, Stony Brook University, Stony Brook NY 11794

Quahog parasite unknown (QPX) has been successfully isolated from clams from different geographic locations in the Northeast. This study uses an *in vitro* approach to investigate the virulence and specificity of various QPX isolates. Interactions between QPX and components from different bivalve species and strains were investigated. Our experiments indicate that QPX growth in *M. mercenaria* is tissue-specific and that some clam tissues possess anti-QPX properties. For example, host foot tissue supports *in vitro* QPX growth while growth in mantle or gill tissue is strongly inhibited. Bivalve plasma also contains anti-QPX factors which may play a role in host defense. Plasma from species not known to develop QPX disease contains higher anti-QPX activity than *M. mercenaria* plasma. Our results also demonstrate that QPX produces extracellular virulence factors that are cytotoxic to *M. mercenaria* hemocytes. This cytotoxicity may play an important role in supporting QPX infection and proliferation within the host. These and future *in vitro* investigations will increase our understanding of QPX infection and disease development. For instance, studies targeting tissues where anti-QPX activities are localized may provide a good strategy for the determination of biological bases of QPX resistance in clams.

NOAA AQUACULTURE PROGRAM UPDATE. Susan M. Bunsick, NOAA Aquaculture Program, 1315 East-West Highway, Silver Spring, MD 20910

As a Federal agency under the U.S. Department of Commerce, the National Oceanic and Atmospheric Administration (NOAA) is focused on creating domestic seafood supply to meet the growing demand for all seafood products. Currently, over 70% of the seafood Americans consume is imported, and at least 40% of those imports are farmed seafood. Domestic aquaculture can be an effective option to reduce dependence on seafood imports, provide jobs for economically depressed coastal communities, and increase

regional food supply and security. For years, NOAA and its partners have worked with coastal communities interested in exploring shellfish and finfish aquaculture as another method to produce seafood, provide jobs and revenues, and use existing seafood processing facilities. As it develops, offshore aquaculture will be one component of the broad NOAA aquaculture program, which currently addresses coastal and onshore marine shellfish and finfish farming. NOAA's Aquaculture Program also includes stock enhancement research and hatchery activities which support commercial and recreational fishing, endangered species and habitat restoration.

DETECTION AND QUANTIFICATION OF NITRATE REDUCTASE IN THE DINOFLAGELLATE, *PROROCENTRUM MINIMUM*. Shanna S. Chambliss and Gulnihal Ozbay, Delaware State University, Department of Agriculture & Natural Resources, 1200 North Dupont Highway, Dover, DE 19901; Gary H. Wikfors, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; and Allen Place, Center of Marine Biotechnology, University of Maryland, Suite 236 Columbus Center, 701 E. Pratt Street, Baltimore, MD 21230

In marine environments, nitrate (NO_3^-) is the major form of inorganic nitrogen used to support primary production. Nitrate reduction to nitrite (NO_2^-) is attributed to nitrate reductase activity. The enzyme nitrate reductase is abundant if phytoplankton are using nitrate to promote growth, but it has been difficult to attribute nitrate reductase activity to specific organisms or groups of phytoplankton.

A new nitrate reductase substrate, 6-chloro-9-nitro-5-oxo-5H-benzo[a]phenoxazine (CNOB), shows promise in this regard. When a nitrate group is cleaved from the CNOB reagent, the remaining molecule precipitates near the site of enzyme activity, thus fluorescently tagging cells with nitrate reductase activity. We quantified CNOB labeling in axenic cultures of dinoflagellate, *Prorocentrum minimum*, to understand how CNOB labeling responds when nitrate levels vary. Axenic batch cultures of *Prorocentrum minimum* were grown in two different media types: medium type one with nitrate, using potassium nitrate (KNO_3) as an inorganic nitrate source and, medium type two with $\frac{1}{4}$ the KNO_3 of standard medium.

Cultures were incubated over a period of 15 days at 20°C on a 12:12 light/dark cycle. On day 15 of the experiment, flow cytometry was used to detect and quantify the amount of CNOB retained in individual cells. Nitrate reductase, as detected by CNOB labeling, is present in cells during the late-log or early-stationary phase. Preliminary results indicate that cells grown in high-nitrate media show higher CNOB fluorescence activity when compared to cells grown in low-nitrate media. Our results indicate that CNOB is an excellent tool for detecting and quantifying nitrate reductase activity in the dinoflagellate, *Prorocentrum minimum*. By using flow

cytometry and CNOB to detect and quantify nitrate reductase activity in this study, we will gain a better understanding of the nutrient status of marine phytoplankton at the cellular level.

COMPARISON OF GROWTH PERFORMANCE OF BAY SCALLOPS (*ARGOPECTEN IRRADIANS*) WITH PHENOTYPES OF DIFFERENT SHELL COLORS. Joseph Choramanski, Sheila Stiles, Dorothy Jeffress and Dionna Williams, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Juvenile bay scallops with phenotypes of different shell colors and patterns from the same genetic line were compared for growth and survival. The phenotypes were divided into three groups: white, striped and the gray/brown typical of bay scallop coloration. Fifteen scallops were placed in 4.0 L beakers with three replicates for each shell color. Groups were further broken into three size classes: 5–7, 8–10 and 11–15 mm. Scallops were held in unfiltered sea water static cultures with aeration at ambient temperature. Beakers were fed daily with an algal mixture of *Tetraselmis* and *Rhodomonas*. Seawater was changed daily and scallops were measured weekly for six weeks. Final mean sizes for all three groups showed good growth, comparable to scallops in running seawater controls. Survival for all groups was above 80% and allowed for adequate sample sizes throughout the experiment. Based on ANOVA, there was no significant difference among the three groups for either growth or survival. This indicates that shell color in general for scallops from the same line is not a significant factor affecting these attributes. These findings also confirmed our previous results from studies that showed no significant difference among bay scallops with various shell phenotypes for growth and survival, including overwintering survival.

IMMUNOMODULATION IN EASTERN OYSTERS, *CRASSOSTREA VIRGINICA*, EXPOSED TO A PAH-CONTAMINATED BENTHIC DIATOM. April N. Croxton^{1,2}, Gary H. Wikfors¹ and Richard D. Gragg, III.² ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Environmental Sciences Institute, Florida A&M University, Tallahassee, FL 32307

Benthic microalgae inhabiting surface sediments play an important role in shellfish-harvesting waters. These roles include sediment stabilization, primary production, and provision of a food source for bivalve species. As a source of nutrition for bivalves, benthic algae are also capable of serving as vectors transferring contaminants from sediments to bivalves. Hydrophobic contaminants can become adsorbed to benthic microalgae in the sediment, and subsequently resuspended microalgae may be ingested by suspension-feeders. This trophic transfer of toxic contaminants can

affect the physiology of a bivalve, including immune defense capabilities.

In this experiment, the effects of PAHs on the immune functions of the eastern oyster, *Crassostrea virginica*, were examined through a microalgal trophic pathway. Oysters were exposed to PAH-contaminated benthic diatoms to examine the effects of this contaminant on oyster immune defense functions. Hemocyte immune-defense functions, including adhesion, oxidative burst, phagocytosis, and viability, were measured using flow-cytometric methods. Significant changes in cellular immune status were associated with PAH exposure. Subsequently, eastern oysters collected from field sites suspected of being contaminated with PAHs will be analyzed to identify correlations in immune responses of these oysters with those exposed experimentally to PAHs in the laboratory. The goal of this research is to employ an ecosystem-based approach to studying the impacts of contaminants associated with a microalgal food source upon a harvestable bivalve species.

PECONIC ESTUARY RESTORATION: A SPAT (SOUTHOLD PROJECT FOR AQUACULTURE TRAINING) ASSISTED PROJECT TO RECLAIM A LOST SCALLOP POPULATION. Armand DeLuca, Otto Schmid, and Kim Tetrault, Cornell Cooperative Extension of Suffolk County Marine Program, Marine Environmental Learning Center, Southold, NY 11971

This presentation described the role of a mature, volunteer community-based, restoration group, *Southold Project for Aquaculture Training (SPAT)*, within a major shellfish restoration project.

This project was initiated in 2004 under a grant by the legislature of Suffolk County on Long Island, NY. The funding, almost \$1.8 M, was designated to support a restoration project with the goal of infusing 50 million scallops into the Peconic Bay Estuary over a period of four years.

As a result of a disastrous brown tide bloom that began in 1985 and occurred sporadically over the following decade, the once prolific scallop population in the Peconics has been reduced to a fraction of its original size. Restoration efforts to date have had only limited success. The theory exists, however, that a much larger reseeding effort might well encourage and jump-start an even-larger natural set. This, then, provided the impetus for the ambitious restoration project to which Cornell Cooperative Extension of Suffolk County (CCE) and Long Island University, NY, committed their efforts.

CCE's responsibility to this project is to provide the seed scallops for grow-out both in containment and for controlled bottom planting in designated sanctuaries in Peconic Bay. This effort includes hatchery and nursery operations and the ongoing maintenance of the juvenile scallops while in containment in open waters.

Long Island University is responsible for technical monitoring and encoding, including genetics and morphometrics, water quality and survival data.

This project has required far more physical resources than previously existed. Cornell Cooperative Extension, with the SPAT volunteers providing much of the labor by logging in 11,437 hours in 2005, has furnished the infrastructure needed to meet the requirements of the project. Over the past year, SPAT volunteers, working with CCE staff, have built a new nursery with raceway tanks, built a new algae room and installed a continuous SEACAPS algae system, constructed a large, fully-equipped 36 foot work barge for field maintenance, and a workshop for various support projects. These efforts have saved CCE hundreds of thousands of dollars by eliminating the need for outside contractors. The volunteers also work with CCE staff in maintaining the shellfish in various forms of containment from the larval stage, through post-set and grow-out, participated in a fall deployment of stock to sanctuaries and in preparing approximately 300,000 scallops for over-wintering in lantern nets for a spring deployment in 2006. The goal of the project is to produce upwards of 10–15 million post-set scallops per year.

ASSESSING DISEASE TOLERANCE IN THE EASTERN OYSTER USING GENE EXPRESSION PROFILING. Elie Diner,¹ Roxanna Smolowitz,¹ Marta Gomez-Chiarri,² Karin A. Tanmi,³ Dale Leavitt³ and Steven Roberts.¹ ¹Marine Biological Laboratory, 7 MBL Street, Woods Hole, MA 02543; ²University of Rhode Island, 20A Woodward Hall, Kingstown, RI 02881; ³Roger Williams University, One Old Ferry Road, Bristol, RI 02809

Oyster populations along the east coast have been devastated by diseases such as Dermo, caused by the parasite *Perkinsus marinus*. Previous research has demonstrated that genetic factors can be selected that contribute to disease resistance in the eastern oyster. The objective of this research is to characterize disease tolerance in local, naturally selected (having experienced heavy disease pressure) oysters in relation to factors such as *P. marinus* infection, growth and genetics. Gene expression profiles have been characterized in oysters that have experienced heavy disease pressure and control oyster populations. Specifically, genes identified as putatively involved in oyster disease resistance were examined using quantitative real-time RT-PCR. One difference observed was with the gene expression patterns for bcl-x, a protein that suppresses the apoptosis pathway. In general, there appears to be an upregulation of apoptosis suppression (bcl-x) in oysters susceptible to Dermo. One interpretation is that oysters that have survived disease outbreaks have an ability to maintain hemocyte numbers at proper levels. Field trials with oysters that have experienced heavy disease pressure and control oysters are underway. Dermo presence has been detected in both groups, however, no significant differ-

ence in growth or mortality has been documented to date. This research is supported in part by the Cooperative State Research Education, and Extension Service, US Department of Agriculture, under Agreement No. 2003-38500-13505.

METABOLIC CONVERSION OF PHYTOSTEROLS TO CHOLESTEROL IN ARTEMIA, A CRUSTACEAN MODEL ORGANISM. Mark S. Dixon,¹ Hui Zhao,² Jose-L. Giner,² and Gary H. Wikfors.¹ ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²State University of New York–ESF, Syracuse, NY 13210

Cholesterol is an essential component of all animal cell membranes. Vertebrate animals are able to synthesize cholesterol from simple precursors, but invertebrates lack this capability and must obtain cholesterol from the diet. Most phytoplankton cells have no cholesterol, but rather a diverse array of related compounds, referred to as phytosterols, as cell-membrane components. Thus, marine invertebrates that feed on phytoplankton are presumed to have abilities to modify some phytosterols to produce the cholesterol that becomes incorporated in their tissues as they grow, but identification of which phytosterols can be metabolized has not been accomplished previously. In this study, we used the brine shrimp, *Artemia*, as a model for crustaceans to explore metabolic capabilities for modifying microalgal phytosterols to cholesterol. Our approach was to enrich a cultured microalga with synthesized, purified phytosterols incorporating stable-isotope-labeled carbon at specific locations in the phytosterol structure, feed these enriched microalgae to brine shrimp, and determine the presence of labeled carbon in cholesterol extracted from the brine shrimp tissues.

The Cryptophyte RHODO (*Rhodomonas* sp.) has only one phytosterol, thus it served as our “blank template” for enrichment. Labeled phytosterols were dissolved in ethanol and incorporated into RHODO cells. The sterol-enriched RHODO was fed to *Artemia* in acrylic cubes filled with 4 liters of filtered seawater. *Artemia* were stocked at 5/ml and RHODO was initially added at 50,000 cells/ml. After 3 days the RHODO was increased to 100,000 cells/ml, and after 3 more days it was increased to 150,000 cells/ml. At the end of the 9-day trial, all *Artemia* were collected on a 100- μ m screen and frozen at -80°C . *Artemia* tissues were extracted and tested for the presence of labeled cholesterol by Nuclear Magnetic Resonance Spectroscopy. Five of eight commonly-occurring phytosterols, including those with both 24-methyl and 24-ethyl substitutions, were converted metabolically to cholesterol by the brine shrimp. By contrast, 24-propylidenecholesterol was neither converted to cholesterol nor accumulated, and two phytosterols associated specifically with dinoflagellates were accumulated but not metabolized. These findings have relevance to the use of crustaceans as live feeds in

aquaculture food chains, as well as to natural trophic interactions between crustacean zooplankton and phytoplankton.

BARNEGAT BAY SHELLFISH RESTORATION PROGRAM: YEAR 1, LEARNING FROM OTHERS. Gef Flimlin and Cara Muscio, Rutgers Cooperative Research and Extension, 1623 Whitesville Rd., Toms River, NJ 08755

Following seven meetings of the International Conference on Shellfish Restoration, Rutgers Cooperative Research and Extension decided that all the proper pieces of the puzzle that are needed for an effective shellfish restoration project, including seriously diminished hard clams stocks, were in place in Ocean County, NJ and that the time was right to muster forces and begin the process. The program was quickly adopted by the Barnegat Bay National Estuary Program as an implementation project for the estuary revitalization process. Great strides were made in the first year following the leads of very successful programs in New York and Delaware with recruiting 35 volunteers, getting local funding of over \$50,000, having significant coverage from the press, documenting each phase of the process, and growing 600,000 hard clam seed in two upweller systems. Seed showed almost four-fold growth in 10 weeks. Mortality was much less than 1%. Seed was placed in ADPI bags in 4 locations for over-wintering and two small-scale research projects are ongoing. One relates to seed density in the over-wintering bags and the other is a study of glycogen content of the seed from the fall to the spring. The volunteer base has become well organized and is taking a leadership role to coordinate more facets of the overall process, including the formation of a 501 (c) (3) non-profit organization to support the program. This program, which is being conducted in conjunction with NJDEP Bureau of Shellfisheries, will continue with hard clams in the next three years as well as establishing 4 oyster reefs and populating them with oysters.

A COOPERATIVE SHELLFISH HATCHERY MODEL: THE SOUND SCHOOL REGIONAL AQUACULTURE CENTER & THE GUILFORD SHELLFISH COMMISSION: SEVEN YEARS LATER. Gabriel N. Geist, Bianca Farrell, Susan T. Murphy, and John J. Roy, Sound School Regional Aquaculture Center, 17 Sea St., New Haven, CT 06519

The Sound School Regional Vocational Aquaculture Center is a comprehensive high school that combines a scientific education with a hands-on training program centered on marine trades and industrial aquaculture. Students are taught a variety of industry-standard aquaculture techniques utilizing both finfish and shellfish in a variety of open and recirculating systems. In addition to classroom and laboratory experience, the Sound School offers both on- and off-site supervised occupational training in aquaculture techniques during summer vacations and after the typical school day

ends. Each student must complete 200 hours of this training each year.

The town of Guilford's Shellfish Commission (GSC) has a long history of wise resource management practice, support for utilization of current research and application of that information to meet the needs of the public. Local support for the GSC is strong and includes not only a well-informed public, but both fisherman and marina owners helping in their management efforts. A rise in license sales in the late 1990's combined with the decline of native oyster populations (due to disease) and hard clams (due to recreational fishing) has made the GSC receptive to alternative stocking efforts including aquaculture. A local support network of the public, businesses and education make the GSC a model program and a viable cooperative effort partner.

In the spring of 1999, the Sound School RVAC and the Guilford Shellfish Commission began a cooperative program to provide bivalve shellfish nursery technician training to high school students. Utilizing student constructed upwellers, the program has produced well over a million hard clams (*Mercenaria mercenaria* x *notata*) and close to a million eastern oysters (*Crassostrea virginica*) for stocking into recreational shellfish grounds in the town of Guilford. A unique blend of industry, education and government has provided shellfish technician training to more than 200 students while expanding the stocking effort and restoring populations of shellfish in Guilford. The program has experienced many 'growing pains' and has undergone several changes over the past few years in an effort to continue. The lessons learned from these experiences will help to provide guidance for the future of this program.

FUNCTIONS OF GRANULAR AND AGRANULAR HEMOCYTES IN EASTERN OYSTERS FOLLOWING FLOW-CYTOMETRIC LIVE-SORTING. Madeleine Gonçalves,¹ Gary H. Wikfors,² Jennifer H. Alix,² and Hélène Hégaret.³ ¹Université de Bretagne Occidentale, Institut Universitaire Européen de la Mer, 29280 Plouzané, France; ²USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ³Department of Marine Sciences, UCONN, Groton, CT 06430

Hemolymph of the eastern oyster contains circulating cells, termed hemocytes, with between two and four distinct morphologies. Within the broad categories of "granular" and "agranular" cells, small and large sub-populations sometimes can be resolved. There are many questions about ontogeny and relationships between these cell types, and information on differences in function between different types of hemocytes is mainly provisional and incomplete. We are attempting to clarify functions in granular and agranular oyster hemocytes by physically sorting them with a BD Biosciences FACS Vantage flow-cytometer and applying function assays (e.g., phagocytosis, respiratory burst) after sorting. Following initial, unsuccessful attempts to obtain sufficient numbers of

viable hemocytes after sorting, we modified test tubes used to collect sorted cells and changed the optical criteria upon which sorting was based. With these modifications, pure suspensions of viable, agranular hemocytes were obtained easily: these cells produced reactive oxygen species (ROS) when stimulated by bacterial extracellular products, but we were unable to detect phagocytosis of plastic microbeads by these cells with either flow-cytometry or fluorescence microscopy. Pure suspensions of sorted granular cells were more difficult to obtain; sort criteria based upon size and internal complexity yielded sorted cell populations comprised of both granular and agranular cells. To test the hypotheses that post-sort agranular cells were degranulated phagocytic cells, we "fed" a whole-hemolymph sample with plastic microbeads to distinguish phagocytic hemocytes, and sorted only the largest, most phagocytic hemocytes into a test tube. Again, a small population of agranular cells was found in the test tube, along with an appreciable number of free microbeads unassociated with hemocytes. Our interpretation is that some phagocytic, granular cells had discharged the microbeads and presumably the granules that distinguish them optically from true hyalinocytes during the sorting process. This preliminary work provides evidence that hyalinocytes in oysters are not phagocytic, but degranulated granulocytes may be indistinguishable optically by the flow cytometer from hyalinocytes.

CONDITION INDEX STUDY OF QUAHOG POPULATIONS IN NARRAGANSETT BAY, RHODE ISLAND. Jeffrey Grant and Michael A. Rice, Department of Fisheries, Animal & Veterinary Science, University of Rhode Island, Kingston, RI 02881

Greenwich Bay, on the western side of Narragansett Bay, Rhode Island is known for its active fishery for the northern quahog, *Mercenaria mercenaria*. Sustained catches of quahogs from Greenwich Bay and adjacent waters suggested that significant annual recruitment occurs, which raised the question as to the location of the parental stocks. Between March and October 20, 2005 quahogs were collected aboard the *F/V Thomi Boy* by bullrake on a monthly basis from 9 different sites around Narragansett Bay, including Greenwich Bay and adjacent coves, Providence River, Allen's Harbor, and conditional shellfishing areas A and B. The condition index of each quahog was determined to help characterize the overall health, and thus the overall potential fecundity of different stocks. The highest condition index values for most of the sites occurred in early June, however the cove areas reached a peak in late May. The mean condition index values ranged from a high of 116.2 in conditional area A in early June to a low of 54.6 in Warwick Cove in March. Conditional area A had the highest average condition index of 98.1, while Warwick Cove and Greenwich Cove had the lowest condition indices of 66.0 and 67.3 respectively. Based on the data collected, the dense assemblages of quahogs in the permanently closed areas may not be as reproduc-

tively healthy as other areas of Narragansett Bay. However, further research is needed to determine if a relationship exists between the condition index and overall fecundity of quahogs in coves and other areas of Narragansett Bay.

EARLY STEAMER CLAM (*MYA ARENARIA*) RESTORATION EFFORTS IN TWO COASTAL PONDS IN OAK BLUFFS, MA (MARTHA'S VINEYARD ISLAND). David W. Grunden and Danielle Ewart, Town of Oak Bluffs Shellfish Department, P. O. Box 1327, Oak Bluffs, MA 02557

The investigation into this project began in 2001 when the Town of Oak Bluffs purchased an axial flow upweller and 200,000 seed (2–3 mm) steamer clams with financial assistance from the Massachusetts Department of Food and Agriculture.

Three trial restoration sites were chosen; two in Sengekontacket Pond and one in Lagoon Pond. One site in Sengekontacket Pond has remained open for harvest. The other two sites are alternated one opening every other year. All three sites are utilized primarily for recreational shellfishing, though occasionally a commercial shellfisherman does harvest from one of the sites in Sengekontacket Pond.

The first year the steamer seed was only grown in the upweller and broadcast seeded at 12–15 mm. The seed at this size dug into the sandy substrate within 15 minutes. The area was marked but ice removed the marker that first winter.

In subsequent years the Town of Oak Bluffs has been able to increase the amount of seed raised to 600,000 in 2005. The Town's Shellfish Department constructed sand-filled nursery rafts to allow for greater growout of the seed. The seed steamers are still removed from the upweller once they reach 12–15 mm, but are now transferred into the nursery rafts where they are held until late mid-September or early October. The seed measured 22.4–38.2 mm when they were planted out in the fall of 2005.

The fishing effort has been monitored by the Shellfish Department and we have seen an increase in the steamer clam landings from these areas since the project began. In 2003 an increase (67.9%) in the number of bushels landed was seen. The landing continued to rise in 2004 and 2005. When the 2002 season is compared to 2005 there has been a 94.87% increase in bushels landed.

CORRELATION OF GONAD INDEX AND GONAD HISTOLOGY AS MEASURES OF SPAWNING ACTIVITY FOR THE BAY SCALLOP, *ARGOPECTEN IRRADIANS*, IN NANTUCKET HARBOR. Valerie A. Hall, Robert S. Kennedy, Peter B. Boyce, W. Forrest Kennedy, Maria Mitchell Association, 4 Vestal Street, Nantucket, MA 02554; Erik Reinbergs and James Sjolund, Nantucket High School, 10 Surfside Road, Nantucket, MA 02554

As part of a larger study conducted by the Nantucket Maria Mitchell Association, the hermaphroditic gonads of 130 bay scallops collected on 18 dates from late July, 2004 through late September, 2005 were processed for histology. After sectioning and staining the paraffin-embedded specimens, microscopic examination was used to determine the stage of gametogenesis and to estimate the average oocyte diameter in the ovarian follicles. These data were correlated with the wet gonad index calculated from newly-dissected scallops collected in the field. A cohort of 25 adult scallops entering their third summer season (22–26 months after spawn) were chosen for special analysis because we were able to examine their gonads throughout their entire reproductive season, late February through late September, 2005. Preliminary comparisons had indicated that the average oocyte diameter exhibited a similar pattern as the gonad index in the wild population of bay scallops sampled in this study. Both parameters appeared to increase before and decrease while spawning occurred. However, further analysis indicated that the two values did not correlate well. Comparing oocyte diameter to gonad index in all 130 scallops, the correlation coefficient (r) was 0.26. For the 25 adults studied through their entire reproductive season, the correlation coefficient (r) was 0.31. Thus, the relationship between gonad index and mean oocyte diameter may not be a good indicator of spawning time in the Nantucket bay scallop. Nevertheless, the progression of the stages of gametogenesis could be traced through the histological studies, suggesting that the third-season scallops did spawn at the time indicated by the drop in gonad index. We need to develop alternate histological methods for determining a scallop's readiness to spawn, using a cohort of scallops from first season of reproduction to the end of their reproductive lifetime.

NORTH CAPE SCALLOP RESTORATION PROJECT- LESSONS LEARNED FROM THE RESTORATION EFFORTS IN RHODE ISLAND'S SOUTH COUNTY SALT PONDS. Boze Hancock,¹ James Turek,¹ Najih Lazar,² and John Catena,³ ¹NOAA Restoration Center, 28 Tarzwell Dr., Narragansett, RI 02882; ² Rhode Island Department of Environmental Management, Division of Fish and Wildlife, 3 Fort Wetherill Rd., Jamestown, RI 02835; ³NOAA Restoration Center, One Blackburn Dr., Gloucester, MA 01930

In January 1996 the tug barge *North Cape* ran aground on the south coast of Rhode Island, releasing 828,000 gallons of No. 2 heating oil. The *North Cape* Restoration Program addresses mul-

tiple shellfish species including bay scallop (*Argopecten irradians*), along with a number of other natural resources injured by the oil spill. The Shellfish Restoration Program is a 5+ year, \$1.5 million effort to restore and enhance bivalve populations in Rhode Island's South County salt ponds and Narragansett Bay, involving federal and state agency staff and local community volunteers.

The initial phase of the scallop restoration project was to survey salt pond habitats, and release farm-raised seed broodstock in suitable habitat areas. Survival and distribution of the scallop releases were monitored during the following season using diver surveys, while the relative abundance, temporal and spatial distribution of settling spat were monitored using artificial spat collectors. Point Judith Pond, one of eight South County salt ponds was chosen as a pilot pond, and in October 2002, ~640,000 scallops (mean size ~30mm) were released. Monitoring during 2003 indicated very low survival and few spat were collected. Diver observations indicated that the high mortality was likely due to predation by crabs and starfish. As each of the semi-enclosed salt ponds presents a unique ecosystem, additional ponds were seeded in late 2003. A total of 2.1 million scallops were released to Potter, Green Hill, Ninigret and Quonochontaug Ponds. Diver surveys in 2004 indicated variable but low survival of these scallop releases. The highest survivorship was in Ninigret Pond where the surviving number was estimated at 9,300 (SE \pm 5,500), or approximately 1.6% of the scallops released.

Low survival of released scallops prompted the establishment of a caged spawner sanctuary, as a second phase of restoration, in 2004. Approximately 10,000 scallop broodstock (1+ year class) were added to Ninigret Pond in spring of 2004. Broodstock were housed in 25, 2' x 2' cages of 1" plastic coated wire mesh, each containing four shelves supporting 1/2" mesh pouches, with 100 scallops per pouch. A July 2004 spawning did not translate into a successful spat settlement, as determined using spat collectors. A modest, late season spatfall was recorded following a spawning in late September 2004, in the area of the broodstock. Scallop abundance surveys in 2005 estimated a substantial population increase, resulting from the 2004 spat-fall, of 132,000 (\pm SE 55,000). This population, along with an additional 10,000 caged broodstock, resulted in a spat-fall throughout Ninigret Pond during 2005 that was 4.5 times the 2004 level. The 2005 spat-fall suggests a similar increase in the abundance of scallops in 2006.

TRANSPORT OF HARMFUL ALGAE VIA RELOCATION OF BIVALVE MOLLUSKS. Hélène Hégaret¹, Sandra E. Shumway,¹ Nicolas Salion,² and Gary H. Wikfors.³ ¹Department of Marine Sciences, UCONN, Groton, CT 06430; ²Produits Elabores Ploermel, 56803 Ploermel, France; ³USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Aquaculture and restoration activities with bivalve molluscs, including oysters, clams, scallops and mussels, often include moving individuals from one body of water to another. Our study tests the hypothesis that harmful algae ingested by source populations of shellfish can be introduced into new environments by means of these shellfish relocations.

Several cultured strains of harmful algae, including *Prorocentrum minimum*, *Alexandrium fundyense* and *Heterosigma akashiwo*, were fed to various species of bivalve molluscs, *Crassostrea virginica* (eastern oyster), *Argopecten irradians* (bay scallop), *Mercenaria mercenaria* (northern quahog = hard clam), and *Mytilus edulis* (blue mussel) to assess the ability of the algal cells to pass intact through the digestive tract of the shellfish and subsequently grow. Shellfish were exposed to the algae at natural bloom concentrations, or to a control of a commonly-used microalgal food, *Rhodomonas* sp., for four hours. Clearance and feeding rates were measured; feces and pseudofeces were collected and observed under the microscope for presence or absence of intact, viable cells or temporary cysts of the algae. Ten bivalves of each species were also exposed for two days to a simulated harmful algal bloom at a natural bloom concentration. The algae were removed after two days of exposure, and bivalves were kept for two more days in ultrafiltered seawater. Biodeposits were collected and observed under the microscope after 24 and 48 additional hours to evaluate again the occurrence and condition of any algal cells. Subsamples of biodeposits were transferred into algal culture medium and filtered seawater and monitored microscopically for algal growth. Intact algal cells of *Prorocentrum minimum*, *Alexandrium fundyense*, and *Heterosigma akashiwo* were seen in biodeposits; generally these re-established growing populations in the first 24 hr after transfer, but less often after 48 hr. These data show evidence that transplanted bivalves may be vectors transporting harmful algae, but a "deuration" step may mitigate this risk.

A PRELIMINARY, FEASIBILITY STUDY FOR COMMERCIAL AQUACULTURE OF *MERCENARIA MERCENARIA* UTILIZING LANTERN NETS VIA A LONG-LINE SYSTEM IN SOUTHWESTERN LONG ISLAND SOUND. Jason Heilwell and Javier Torres, Bridgeport Regional Vocational Aquaculture School, 60 Saint Stephens Rd., Bridgeport, CT 06605

This project is designed to determine if Chinese-style lantern nets are a commercially feasible method for cultivating *Mercenaria mercenaria*. Dually, the data will also indicate if *Mercenaria mercenaria* will demonstrate a higher growth rate in the photic or aphotic zone. The lantern nets are suspended from a long-line to a depth of one meter below the water surface. The two hundred forty foot long-line is deployed approximately one-half mile off the coast of Jennings Beach, Fairfield, CT. The preliminary data analysis consisted of comparing weekly mean height measure-

ments of a five thousand, member test population. From September 13, 2005 until February 10, 2006 the mean height of the *Mercentaria mercenaria* increased from 17 mm. to 19.95 mm, demonstrating a mean height increase of 2.95 mm, indicating a daily growth rate of .0189 mm. The initial water temperature on September 13, 2005 was 16°C and as of February 10, 2006 was 3.2°C. In comparison, *Mercentaria mercenaria* cultivated via traditional clam beds demonstrated a daily growth rate of 0.09mm, at a temperature of no less than 15°C. Biofouling and weather related system damage are the initial operational drawbacks of the project. Future plans are to continue weekly sample measurements of the *Mercentaria mercenaria* and to continue observation of the system mechanics. Anticipated project revisions included the use of sea clams directly transferred from an upweller system to the lantern nets.

MONITORING THE RESTORATION OF THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA* IN RHODE ISLAND.

Jason Helyer,¹ Boze Hancock,² Jim Turek,² Najih Lazar,³ and John Catena,⁴ ¹University of Rhode Island, N. Kingston, RI 02881; ² NOAA Restoration Center, 28 Tarzwell Dr., Narragansett, RI 02882; ³ Rhode Department of Environmental Management, Division of Fish and Wildlife, 3 Wetherhill Rd., Jamestown, RI 02835; ⁴NOAA Restoration Center, 1 Blackburn Dr., Gloucester, MA 01930

The North Cape Shellfish Restoration Program is rebuilding oyster populations in Rhode Island by seeding juvenile oysters. The program has seeded approximately 2.4 million juvenile oysters at six restoration sites since 2003. This study evaluated oyster restoration efforts by analyzing survival data, growth rates, and the presence of oyster disease in two cohorts of seeded oysters: 2003 and 2004.

Comparisons between survival, disease, and annual growth do not suggest any clear explanations for the decrease in oysters at two of the restoration sites, or the higher survival rates at the other four sites. Results suggest that disease is not affecting oyster survival as the two sites with the highest incidence of *Perkinsus marinus* also have the highest survival and growth rates. Future sampling done in both early summer and fall may provide better insight as to the temporal pattern of mortality as well as providing information about factors influencing oyster survival.

EVIDENCE OF LONG ISLAND SOUND OYSTER HEMOCYTE MICRONUCLEATION AS MEASURED BY FLOW CYTOMETRY. James B. Hughes, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Eastern oysters (*Crassostrea virginica*) are found in coastal Connecticut marine habitats that are chronically affected by contaminants. The chromosomal damage in the form of breakage,

rearrangement and misdivision that results from this exposure, can be monitored indirectly using the micronucleus test. Micronuclei are small, intracytoplasmic pieces of chromatin that are either chromosome fragments that lack centromeres or complete chromosomes that lagged at anaphase due to spindle defects. Except for their small size, they resemble the major nucleus. The micronucleus test is an internationally recognized system for the detection of the clastogenic/aneugenic effects of compounds. Examination of micronuclear incidence has progressed from time-consuming microscopic analyses to a faster, more statistically thorough method through the use of flow cytometry.

Oysters were sampled during October–November, 2004 at 13 sites along the northern shore of the Long Island Sound from Darien, CT to Fishers Island, NY. Ten oysters were collected at each site and brought to Milford where they were held overnight prior to the collection of their hemolymph. Oyster hemolymph was drawn using 1.0 ml tuberculin syringes and placed in 1.5 ml microcentrifuge tubes on ice. A 100 µl aliquot of hemolymph from each oyster was transferred to 5.0 ml cytometer tubes along with 4.0 µl SybrGreen, 4.0 µl propidium iodide, and 100.0 µl of filtered sea water. Samples were analyzed using a BD Biosciences FACSCAN flow cytometer. Coefficient of variation of SYBRGreen fluorescence data were analyzed using Kruskal-Wallis one-way nonparametric analysis of variance test (STATISTIX 7.0).

Of the 13 sites, 8 were significantly different from each other, whereas 5 were statistically homogeneous. The Milford, CT site showed the lowest nuclear variance and was significantly less ($p < 0.0002$) impacted than Scott's Cove in Darien, CT, which had the highest variance.

PRODUCTION METHODS FOR THE VENETIAN SOFT SHELL SHORE CRAB ("LE MOLECHE"). Richard C. Karney Martha's Vineyard Shellfish Group, Inc., Box 1552, Oak Bluffs, MA 02557; Robert D. Garrison, Wampanoag Aquinnah Shellfish Hatchery, 20 Black Brook Rd., Aquinnah, MA 02535

The production of "le moleche," the soft shell, green shore crab, *Carcinus aestuarii* is centered in the Adriatic seaport town of Chioggia, Italy at the south end of the Venice Lagoon. The fishery supports a local industry that employs over 220 fishermen and is valued at \$3.5 million. Fishermen receive about 35 euros per kilo for the molted crabs that are an important part of the local cuisine. Using methods that have changed little since the Middle Ages, crabs are caught in pound nets, segregated according to expected time to molting, and held to shed in submerged keepers. Key to successful production is the recognition of visual clues that signal the onset of ecdysis; knowledge traditionally passed from father to son. The application of the molting techniques used by the Italian industry to the production of soft shell green crabs using the species *Carcinus maenas* holds promise for development of a similar industry in the US.

UPDATE ON NOAA'S NON-NATIVE OYSTER RESEARCH PROGRAM IN SUPPORT OF THE CHESAPEAKE BAY OYSTER EIS. Jamie L. King, NOAA Chesapeake Bay Office, 410 Severn Ave., Suite 107, Annapolis, MD 21403

Federal and state agencies continue to prepare an Environmental Impact Statement (EIS) to evaluate the proposed introduction of a non-native oyster, *Crassostrea ariakensis*, in Maryland and Virginia waters. As a Cooperating Agency on the EIS, NOAA is conducting a 3-year, \$6M competitive grants program. This Non-native Oyster Research Program is currently in its second year, and is aimed at research priorities previously identified by the National Research Council and the Chesapeake Bay Scientific and Technical Advisory Committee. Although the research program's third and final year (FY06) will continue to fund projects through 2007, NOAA's objective is to facilitate the rapid transfer of new findings to the peer-reviewed literature to support EIS evaluations as the research progresses.

Toward this end, the NOAA Chesapeake Bay Office is sponsoring Quarterly Reviews to provide a forum for sharing and discussing the most current research findings and to ensure timely incorporation of research results into the EIS evaluations. The first review session was held in Spring 2005, and covered a variety of topics including *Crassostrea ariakensis* taxonomy and genetics; susceptibility to oyster diseases such as *Bonamia*, Dermo, and MSX; and basic life history and ecology. The Summer 2005 Quarterly Review focused on 'Aquaculture options: Biological and economic factors affecting aquaculture production of native and non-native oysters in the mid-Atlantic.' The Fall 2005 Quarterly Review addressed 'Potential for *C. ariakensis*–*C. virginica* interactions: Larval substrate selection, post-settlement competition, and fertilization interference.' Reports summarizing the preliminary findings presented at these review sessions are available at the NOAA Chesapeake Bay Office.

The NOAA Chesapeake Bay Office will also sponsor a special session on non-native oyster research at the 98th Annual Meeting of the National Shellfisheries Association. The session will culminate in publication of a special edition of the Journal of Shellfish Research. NOAA is funding the special session and journal volume to facilitate the rapid transfer of new findings to the peer-reviewed literature to support EIS evaluations as the research progresses.

DIFFERENCES IN PROTEIN EXCRETION BY THE HARMFUL MARINE DINOFLAGELLATE, *PROROCENTRUM MINIMUM*, UNDER DIFFERENT CULTURE CONDITIONS, AS REVEALED BY SELDI PROTEOMIC TECHNOLOGY. Yaqin Li,¹ Hélène Hégaret,² Shannon L. Meseck,¹ Gary H. Wikfors,¹ Mark S. Dixon,¹ and Jennifer H. Alix,¹

¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460;

²Department of Marine Sciences, UCONN, Groton, CT 06430

The dinoflagellate *Prorocentrum minimum* is listed among the "HAB" (Harmful Algal Bloom) phytoplankton because it sometimes is associated with harmful effects upon shellfish and other marine life in coastal waters. Studies with cultured isolates of this species have revealed a diverse array of bioactive effects, including inhibition of bacterial growth, allelopathic effects on other phytoplankton species; in feeding bivalve mollusks, altered feeding behavior, tissue pathologies, immunomodulation and mortality; and toxicity of cell extracts when injected into mice. Other studies have shown no bioactive effects of *P. minimum* cultures, leading to speculation that strains may differ in toxicity, or expression of toxicity is dependent upon physiological status of the population which is affected strongly by environmental and chemical conditions. Moreover, chemical identities of all toxic agents in *P. minimum* remain poorly known.

The present experiment was designed to investigate differential expression of proteins or peptides excreted into the media by *P. minimum* cells cultured under experimentally varied conditions: nutrient and gas replete, P-depleted, or air-restricted. Excreted proteins were analyzed using a relatively-new technology, SELDI (surface-enhanced laser desorption-ionization) time-of-flight mass spectrometry. SELDI utilizes protein chip array technology to separate proteins from complex mixtures with high resolution. Mass spectrometry is used to detect proteins that are selectively adsorbed to "chip" surfaces of different chromatographic surfaces while impurities are washed away. Of a total of over 20 different proteins and peptides detected in *P. minimum* culture media, the majority were present in all treatments, suggesting that these most-likely are normal, metabolic by-products. Gas restriction resulted in increased quantities of five proteins and decreased amount of six proteins compared to control. P-depleted cultures showed significant increases in four proteins and a decrease in one protein. A protein with M/Z 9235 was up-regulated in both gas-restricted and P-depleted treatments, relative to the control, suggesting the possibility that this is a general stress response. The changes in the protein profiles under different conditions may represent a number of physiological responses to protein level. For example, changes in proteins may involve cells switching from autotrophic to heterotrophic metabolic mode under air restricted condition. While under P-depleted situation, such changes in protein may involve the production of diketone, a breakdown product of carotenoid.

PROGRESS IN ISOLATION AND EVALUATION OF NEW, PROBIOTIC BACTERIA FOR USE IN SHELLFISH HATCHERIES. Hyun Jeong Lim,¹ Diane Kapareiko,² Steven Pitchford,² Jennifer H. Alix,² Shannon L. Meseck,² Mark S. Dixon and Gary H. Wikfors.² ¹Aquaculture Division, West Sea Fisheries Research Institute, Incheon 400-420, South Korea; ²USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Hatchery production of shellfish seed is necessary to supplement natural recruitment which is constrained by various stresses including habitat loss, pollutant contamination, overfishing, and climate fluctuations. Bacterial diseases are considered to be a major cause of mortality in shellfish larviculture and hatcheries, however, over-use of antimicrobials can result in development of resistant strains of bacterial pathogens. The use of probiotics for disease prevention and improved nutrition in aquaculture is becoming increasingly popular as the demand for environmentally-friendly aquaculture grows. This study, therefore, has the objectives to isolate and evaluate efficacy of new probiotic bacteria and microalgae for use in shellfish hatcheries.

First, 26 probiotic-candidate bacteria were isolated from oysters, scallops, and a mass culture of green algae. Sixteen of these isolates inhibited known scallop-pathogen bacterial strains, B183 and B122, in disc-diffusion assays: 9 strains were from oysters, and 7 strains from scallops. Oyster larvae were exposed to these 16 probiotic candidates for 48 hours to determine possible positive effects on survival. Similar to the control (unchallenged oyster larvae), larval survival was >90% with all probiotic candidates. We then re-isolated the probiotic candidates from larval challenges and confirmed identities by gram stain, morphology, and Biolog, finding 7 distinct strains according to these criteria. Using a 12-well, microplate method, we performed further larval challenges to see if the probiotic candidates had a positive effect on larvae and suppression of mortality caused by the pathogen B183. Oyster larvae exposed to one probiotic candidate (Oy-15) had the highest survival rate, and further, addition of this probiotic candidate to oyster larvae challenged with the pathogen improved survival compared to the pathogen alone.

In addition to the bacterial strains, we also isolated 3 microalgae from Long Island Sound during oyster-spawning season using sorting flow-cytometry. We determined algal division rates to assess suitability for mass culture and eventual mixed culture with probiotic bacteria. Probiotic-bacteria candidates did not have negative effects upon the newly-isolated microalgae; however, *Isochrysis* sp., T-ISO, grew significantly slower when grown with the probiotic-candidate strain G1 than when grown bacteria-free.

In the future, we will confirm positive effects of our probiotic candidates during long-term rearing of oyster larvae and also determine nutritional value of mixed cultures of the new microalgal and probiotic bacterial strains. This study can be the basis for development of functional foods that incorporate probiotics in shellfish hatcheries.

HYBRIDIZATION BETWEEN TWO DIFFERENT GENERA OF CLAMS, *SPISULA SOLIDISSIMA* AND *MULINIA LATERALIS*, AND EARLY GROWTH TRIALS. Scott Lindell, Bethany Walton and Janice Simmons, Marine Biological Laboratory, Woods Hole, Massachusetts 02543

The Atlantic surf clam (*Spisula solidissima*) and the coot clam (*Mulinia lateralis*) occupy different habitat niches along the eastern North American seaboard. The Atlantic surf clam supports a multi-million dollar fishery and has been the subject of pilot-scale commercial aquaculture. Among the interesting properties of the coot clam that have made it useful to biologists are its ease of culture, short generation time, and high rate of reproduction. Despite their apparent geographic and reproductive isolation we have cross-bred these two species in the lab. Larvae of coot clams and both hybrids (*Spisula* eggs x *Mulinia* sperm and *Mulinia* eggs by *Spisula* sperm) metamorphosed at 10 days at 20°C and were then reared on set screens and in sand substrate. Results of the first four months of growth of the hybrids and *Mulinia lateralis* have implications for reassessing the taxonomy of mactrid clam species, and may hold promise for a new aquaculture species.

INVESTIGATION OF GENETIC VARIABILITY OF QPX, A PATHOGEN OF THE HARD CLAM, *MERCENARIA MERCENARIA*. Qianqian Liu, Bassem Allam and Jackie Collier, Marine Sciences Research Center, Stony Brook University, Stony Brook, NY 11794

QPX (Quahog Parasite Unknown), a protistan parasite of the hard clam *Mercenaria mercenaria*, has caused significant mortality of hard clam stocks in many locations along the east coast of the United States and Maritime Provinces of Canada since the 1960's. In the summer of 2002, an outbreak of QPX disease occurred in New York, causing severe economical losses. In this study, we used different QPX isolates to evaluate the molecular genetic variability among QPX organisms obtained from different geographical locations. Investigated isolates included QPX obtained from New York clams in 2003 and 2004, the isolate ATCC 50749 initially obtained from Massachusetts clams in the late 1990's, and new isolates obtained from Massachusetts clams in summer 2005. Our data showed that in the 18S and 28S ribosomal genes, slight sequence variations exist in some isolates. At the same time, a complex pattern of sequence variations was found in the Internal Transcribed Spacer genes ITS1 and ITS2: the variability within a single QPX isolate is as great as that among the different isolates, suggesting that these multi-copy genes might not be a good choice to investigate QPX genetic variability on the strain level. Four mitochondrial protein-coding genes (NADH dehydrogenase subunit 1 and subunit 7; Cytochrome oxidase subunit 1 and Cytochrome b) showed no sequence variability among the four investigated isolates (two from NY 2003, 1 from MA 2005 and MA ATCC 50749). The significance of the variations observed in the 18S and 28S genes needs to be further studied.

ASSESSMENT OF THE SETTLEMENT, GROWTH, AND SURVIVAL RATE OF THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*) ON STRINGS WITH SURF CLAM CULTCH AND STRINGS WITH SEA SCALLOP CULTCH.

Kady Marino, Karin A. Tammi, Christopher Davis, Johanna Fay, Timothy Scott and Dale Leavitt, Center for Economic and Environmental Development, Roger Williams University, 1 Old Ferry Rd., Bristol, RI 02809

Traditionally, southern New England has been a major commercial source of oysters, specifically the eastern oyster (*Crassostrea virginica*). However, a series of events including hurricanes and disease has greatly harmed the industry in New England. The disease Dermo, caused by the protozoan *Perkinsus marinus*, is the most prevalent observed oyster disease in Rhode Island, and is largely responsible for low survival rates among oysters in Narragansett Bay. After a record low oyster yield in 1961, *C. virginica* began to make a comeback in Rhode Island waters in the early 1990s. A common method of oyster fisheries has been that of remote setting. The string method of setting has declined in popularity in recent years but has been the preferred larval setting mechanism of Luther H. Blount for decades. The aim of this research is to assess the benefits and feasibility of the string method by monitoring settlement, growth, and survival of eastern oyster spat when set on strings with surf clam and scallop cultch. The spat was monitored on Prudence Island through the summer and fall and was tested using RFTM and Ray's tissue assay for the protozoan *P. marinus*.

Our analysis of variance results indicated no difference in settlement for shell type (sea scallop or surf clam). However, larval settlement was significantly different depending upon horizontal and vertical placement of the strings within the tank, most likely due to light penetration and larval settlement behavior and air flow dynamics.

CHANGES IN FEEDING AND EXCRETION RATES OF BAY SCALLOPS, *ARGOPECTEN IRRADIANS*, WHEN EXPOSED TO ELEVATED LEVELS OF AMMONIA IN A CLOSED SYSTEM. Shannon L. Meseck, James C. Widman Jr., Lisa M. Milke, George Sennefelder, Mark S. Dixon, Diane Kapareiko and David J. Veilleux, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Good water quality is crucial to high survival and growth rates of bivalves held in closed or semi-closed rearing systems. As concentrations of nitrogenous waste increase in seawater systems, these compounds can become toxic. In a scallop nursery system, removal and addition of nitrogen can occur through numerous pathways. For example, removal of nitrogen can be attributed to phytoplankton uptake, while the main inputs of nitrogen are often through waste production from the scallops. The atmosphere can also act as an important source or sink of nitrogen depending on a

variety of factors, including concentration gradients and mixing. This study was designed to examine the sources and sinks of ammonia in a closed system used to grow bay scallops. The study further examined if high concentrations of ammonia would result in changes to those removal or input factors.

Bay scallops, ranging in size from 8 mm to 12 mm, were placed in buckets with 8 L of water for 24 hours, where they were fed every four hours, so that by the end of 24 hours they had been fed 2% of their live, whole-body weight. Every four hours, samples were taken to monitor the change in ammonia over time. The scallops were exposed to one of three levels of total ammonia: ambient seawater concentrations ($<0.01 \text{ mg L}^{-1}$), 1.5 mg L^{-1} , and 4.0 mg L^{-1} .

For each of the buckets, removal rate by phytoplankton utilization, excretion from scallops, and other inputs/outputs were monitored. Results from the experiment suggest that the removal of ammonia via phytoplankton uptake did not change at higher ammonia concentrations. However, at the higher ammonia concentrations, there was a large loss attributable to atmospheric exchange, bacterial uptake, and/or adhesion of ammonia to surfaces of the containers. The input of ammonia via excretion from the scallops appears to remain similar at different ammonia levels. This short-term study suggests that the interaction of input and outputs of ammonia in a closed system is complex; however, scallop excretion and phytoplankton uptake of ammonia appear to be constant for a wide range of ammonia concentrations.

***TETRASELMIS CHUI* (PLY429) DIVISION RATE AND UPTAKE OF NITRATE AND PHOSPHATE AT EXPERIMENTALLY-VARIED PII.** Shannon L. Meseck, Jennifer H. Alix, Mark S. Dixon, Barry C. Smith and Gary H. Wikfors, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Mass cultures of phytoplankton are complex because growth is dependent upon a number of variables, including pH, light intensity, day length, nutrient availability, and temperature. In high-volume mass cultures of microalgae (e.g., 18,000-L tanks), at the NMFS Laboratory in Milford, a contaminating microalga can often be observed growing with *Tetraselmis chui* (PLY429—an algal strain used widely as an aquaculture feed) and can dominate the culture eventually. The succession of one algal species to another may be a consequence of differing light, nutrient, temperature, and pH requirements of the competing species. This study is the first part of an investigation on how pH can affect the succession of one algal species to another. The results presented focus on the effects that pH has on the growth of and uptake of nutrients by *Tetraselmis chui* (PLY429).

Tetraselmis chui cultures were grown aseptically in 2L carboys of F media at a temperature of 19.5°C , a light intensity of $110 \mu\text{Einst. m}^{-2} \text{ s}^{-1}$, with a light dark cycle of 16:8. The experiment was run at the following pH's: 6.23, 7.26, 8.07, 9.03, and 9.32 with

the initial pH's obtained by adding either hydrochloric acid or sodium hydroxide to the carboys. During the experiment, the pH was maintained at ± 0.2 pH units by the addition of carbon dioxide to the carboys. The pH did significantly affect the division rate ($P < 0.01$) of PLY429. At the lowest pH, division rates were 0.37 d^{-1} ; whereas, division rate was 0.88 d^{-1} at a pH of 7.26. Fitting the data to a division rate curve revealed that the optimal growth of PLY429 occurs at a pH of approximately 7.8. Uptake of nitrate and phosphate per cell indicates that the pH had no significant effect on the utilization of nitrate ($P = 0.71$); however, there was a significant effect of pH on the loss of dissolved phosphate in the cultures ($P = 0.04$). Loss of dissolved phosphate from the media at pHs of 6.23, 9.03, and 9.32 were statistically indistinguishable and greater than at the other pH's. Unlike nitrate, phosphate can complex with other chemicals in the media (i.e., calcium, magnesium, sodium, and iron) and render it less bioavailable for phytoplankton uptake. Phosphate complex formation with these chemicals is dependent upon their relative concentrations and upon the pH of the media. Our data suggest that in the cultures in which pH was near 6 or above 9, phosphate may have reacted with other chemicals in the media to form complexes that were not available to the phytoplankton for growth. Thus, PLY429 may be at a competitive disadvantage if pH is outside of the optimal range, rendering it more susceptible to domination by microalgal contaminants.

CHANGES IN ENZYMATIC ACTIVITY DURING EARLY DEVELOPMENT OF BAY AND SEA SCALLOPS, *ARGOPECTEN IRRADIANS* AND *PLACOPECTEN MAGELLANICUS*. Lisa M. Milke, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; V. Monica Bricelj and Neil W. Ross, National Research Council, Institute for Marine Biosciences, 1411 Oxford Street, Halifax, NS B3H 3Z1 Canada

Poor growth and survival of postlarval scallops is often observed in hatcheries during post-metamorphic development when they undergo marked morphological changes and may thus be particularly vulnerable to dietary deficiencies. Although stage- and species-specific differences in dietary requirements have been demonstrated, the mechanisms responsible for differential diet performance remain largely unexplained. While biochemical composition is central to assessing the nutritional value of a diet, an animal's digestive and assimilation capacity are equally important. Digestive capacity of sea and bay scallops may differ 1) over development in association with morphological changes, and 2) between species, as these two species are adapted to different environmental conditions and food supply.

To test these hypotheses, scallop postlarvae [initial shell height (SH) $\sim 250 \mu\text{m}$] were reared on a mixed algal diet consisting of one diatom (*Chaetoceros muelleri*) and one flagellate (*Pyrova* sp. CCMP 459 or *Pyrova pinguis*) until 4–5 mm SH, and were sampled at intervals coinciding with major morphological changes.

A series of colorimetric assays were conducted to measure the specific activity of carbohydrases (laminarinase, cellulase and alpha-amylase), proteases (azocasein and cathepsin B) and lipase (esterase) in scallop tissues.

Preliminary findings do not indicate any trends in protease or lipase activity either over time or between species; however, clear patterns in carbohydrase activity were observed. Sea scallops exhibited higher laminarinase activity, but lower levels of alpha-amylase and cellulase activity than bay scallops, with the most pronounced changes in enzymatic activity occurring in both scallop species prior to attaining ~ 1.2 mm SH. However, laminarinase activity was significantly higher than activities of either alpha-amylase or cellulase in both scallop species. This is consistent with previous reports of higher activities of laminarinase than alpha-amylase in adult sea scallop digestive glands. Interestingly, lower activities of laminarinase than either alpha-amylase or cellulase, were reported in digestive glands of adult bay scallops, further indicating that enzymatic activity may vary among scallop developmental stages and species. Our findings have implications for developing targeted diets that could optimize postlarval scallop growth and survival in commercial hatcheries and for understanding utilization of the natural food supply.

DEVELOPMENT OF A SUBMERSIBLE MUSSEL RAFT.

Dana Morse, Maine Sea Grant, Darling Marine Center, Walpole, ME 04573; Babe Stanley, Shaba Shellfish, 42 Old Mill Stream Road, Sullivan, ME 04664; and John Riley, University of Maine, Norman Smith Hall, Orono, ME 04469

In recent years, mussel producers in Maine have focused on floating rafts as the preferred method of suspension culture, augmenting the already substantial production of bottom-raised product. Raft culture produces a high quality mussel, and is relatively protected against predation from the large population eider ducks in the state. However, rafts have the twin drawbacks of potentially impacting navigation and scenery, and also of suffering damage from icy or otherwise extreme weather conditions.

In 2003, an idea came from industry to develop a submersible version of a mussel raft, and a group came together to support this idea, consisting of industry, engineering, conservation, homeowners and extension. The design incorporates a set of hollow pontoons with steel or aluminum cross pieces, and surface buoys. Air is pumped in or out of the pontoons, and the surface buoys regulate height below the surface, and absorb surface energy.

A scale model was tested in the Tow Tank at the University of Maine in 2004, and early results indicated that the concept had potential. Follow up to the model trials has included fundraising to build half- and full-scale versions of the rafts, and a full scale prototype is presently undergoing initial field trials. The advancement of this idea has implications for both the production methods used in the state, and its acceptance by potentially competing user groups.

SEEKING THE MOST INTELLIGENT DESIGN: THE EARLY EVOLUTION OF OYSTER GARDENS IN MAINE.

Dana Morse, Maine Sea Grant, Darling Marine Center, Walpole, ME 04573; **Chris Davis**, Maine Aquaculture Innovation Center, University of Maine, Corbett Hall, Orono, ME 04469

A two-year oyster gardening program in Maine was initiated in 2004, and the inaugural class completed its work in September of 2005. Students received approximately 20 hours of classwork early in 2004, and began field activities in July of that year. Each student purchased equipment sufficient for floating culture of 1000 seed oysters, and was given assistance in the construction, deployment and maintenance of the floating bags and the oysters. Sites to accommodate these activities were obtained through the Limited Purpose Aquaculture License, as administered by the Maine Department of Marine Resources.

The program was successful in raising oysters, and the students have obtained an excellent education in relevant marine issues, as well as being enthusiastic consumers of their home-grown product. However, critical issues remain, if such an approach can be successful in the long-term in Maine. For example, how do we accommodate the continued interest in the program, without having an undue effect on space available to the commercial industry and to other users of the waterways? How can such programs be taught effectively, over large geographic distances? Discussions have taken place between the project partners, industry members and others, to ensure that the benefits of the oyster garden program in Maine are not outweighed by negative outcomes. One option, the development of community gardens, will be implemented for the next class, anticipated to begin in April of 2006.

A HATCHERY EXPANDS TO HELP RESTORE BAY SCALLOP, *ARGOPECTEN IRRADIANS*, POPULATIONS AND FISHERIES IN NEW YORK.

R. Michael Patricio, Cornell Cooperative Extension of Suffolk County, 3690 Cedar Beach Road, Southold, NY 11971

The near total collapse of bay scallop populations and the historic fishery it supported, on Eastern Long Island, New York has prompted funding of a large scale restoration program. This four year effort will require raising production levels from 1 million to 10–20 million animals, annually. Although the hatchery has been in operation since 1991, this project will necessitate considerable expansion of all aspects of production. The hatchery has been using batch algae culture for many years, however, to meet the demands of our restoration project, a continuous algal production system was put in place.

A Seasalter Continuous Algal Production Systems (SeaCAPS), system was installed to provide the volume of algae needed to increase the hatchery's production. This system was chosen because it could provide not only the volume needed for the project, but also a constant supply of higher quality algae compared to the batch culture system.

An expanded post-set growing facility was built to provide enough space for scallops that range from 250 microns to 2 mm. Juvenile scallops are placed on downweller sieves and receive coarsely filtered water which is free from macroplankton; a rotary drum filter was utilized to provide filtered (<100 μ) seawater. Scallops (>2 mm) will be placed in spat bags for continued growth up to 10 mm. A portion of the 10+ mm scallops will be free-planted, while the rest will continue to grow in lantern nets to be used the following year as spawner sanctuary stock. It is expected that the expansion and improvement of our facility will meet the needs of the restoration program and help return the scallop fishery to Eastern Long Island.

PROGRESS AT THE SOUND SCHOOL AQUACULTURE CENTER'S LOBSTER HATCHERY.

Elyse R. Rabinoff, John J. Roy and Angel G. Santiago, Sound School Regional Aquaculture Center, 17 Sea St., New Haven, CT 06519

Believed to be the first lobster hatchery operated by high school students in the nation, the Interdistrict Marine Educational Program's Instructional Lobster Hatchery (IMEP/ILH) is designed to provide high school students with an opportunity for the enhancement of knowledge in aquaculture and marine sciences. The development of "hands on" curricula assists students in applying lessons to "real world" situations. The program is funded by the Office of Urban and Priority School districts, the Connecticut State Department of Education as a Continuing Interdistrict Cooperative Grant and is administered by the Science Department at the Sound School.

The Lobster Hatchery Program was initiated in 2002 with technical advice coming from the University of Rhode Island. From the inception, the lobster hatchery program has been supported through a cooperative working relationship with the students and staff at Ella T. Grasso/Southeastern Regional Vocational Technical School in Groton. It was anticipated from the onset that the ILH would be a multiyear undertaking. Progress with propagation would be realized in incremental steps as more experience was gained with lobster husbandry.

During the past five years, the lobster hatchery has undergone several changes both in location and equipment design. The initial goals for the program have been met. Broodstock (*Homarus americanus*) have been successfully held, and viable young have been produced. Each year the students who are involved in the ILH make advances based on the work of the preceeding years' participants. Cannibalism is a major obstacle to successful lobster culture. Last year's primary objective was to have ten larvae survive past the fourth instar. During March and April of 2005, students collected, counted and sorted 3,852 viable larvae from the broodstock tanks. Young animals were fed enriched *Artemia* daily. The young were counted every other day and monitored for developmental advancement. Thirty-four animals had reached the fourth instar when a chiller malfunctioned killing all but two of the

juvenile lobsters. We were successful in keeping those animals alive until September of 2005.

This season we will incorporate what was learned last spring and implement some modifications in collection and culture techniques that should allow more individuals to reach the benthic stage. Our objective will be to have one hundred animals survive to reach the fourth instar. Within the next few years, it is expected that a portion of the juveniles produced will reach adulthood. As techniques continue to advance, the juveniles that are produced will be made available to both educational and aquacultural researchers. In the future, it is anticipated that the IMEP/ILII will become a reliable source of known-aged lobsters that can be used for research. We hope that these animals will help establish successful ventures in lobster culture that may one day serve to lessen the demands on the wild population of lobsters in Long Island Sound.

THE ATTACHMENT STRENGTH OF *MYTILUS EDULIS* AND THE STRENGTH/LENGTH RELATIONSHIP. James F. Reinhardt and Sean P. Grace, Southern Connecticut State University, 501 Crescent St., New Haven, CT 06515

A mussel's ability to remain attached to the substrate is contingent on its ability to attach at a greater strength than the maximum hydrodynamic force to which it is exposed. For mussels located in a bed, lift is often considered the hydrodynamic force most responsible for dislodgement. The force of lift is proportional to the surface area that the force acts upon, and can be approximated as the area of an ellipse. Lift is also proportional to the square of the velocity of water moving over the mussel. In order to accurately predict size based differences in the probability of dislodgement it is necessary to understand how attachment strength varies as size increases. This size-strength relationship must be put into the context of time, because both attachment strength and wave climate vary temporally. Climatologists have predicted an increase in hurricane activity, including an earlier start to the hurricane season. Given the predictions, it can be expected that greater wave energies may occur during the late summer months, when mussel attachment strengths are at their lowest.

To understand better how changes in wave climate may affect mussel dislodgment, attachment strengths of *Mytilus edulis* were measured at two different sites: 1) a protected site (Southport, CT) and 2) a wave exposed site (Jamestown, RI) monthly during spring tides, over the past year. There were significant differences in the attachment strength between sites and attachment strength covaried significantly with size. Information gained from this study is important in understanding how increased wave energies during late summer months may affect dislodgment rates of the blue mussel.

EAST COAST SHELLFISH GROWERS ASSOCIATION—POLITICS, POLICIES AND PROGRAMS THAT AFFECT YOU! Ed Rhodes, Executive Director, East Coast Shellfish Growers Association, Rutgers Cooperative Extension, 1623 Whitesville Rd., Toms River, NJ 08755

The East Coast Shellfish Growers Association (ECSGA) was born at a Milford Aquaculture Seminar four years ago. The ECSGA is now composed of about a hundred shellfish companies of all sizes from all of the Atlantic coastal states and includes a number of researchers and others with an interest in shellfish aquaculture. In 2005 the ECSGA was directly involved in a number of national issues that affect the shellfish industry and ECSGA members made four trips to D.C. to help educate Congress and Federal Agencies. In January during the annual all-coasts shellfish "Walk-on-the-Hill" 6 ECSGA members visited 17 senators and representatives over a 3-day period and discussed the need for a more coordinated approach by Federal agency interactions on shellfish issues, the erosion of aquaculture funding by both the National Oceanic and Atmospheric Administration (NOAA) and the Department of Agriculture, country of origin labeling definitions of "wild" and "farm-raised" shellfish, the EPA sewage blending proposal that would reduce standards for treatment plants, the need for good science to address the introduction of the non-native *Crassostrea ariakensis* species, and the need for Federal assistance in shellfish marketing and crop insurance.

Two months later we were back in D.C. following the acceptance by NOAA of the petition for an Endangered Species Act listing of the American oyster and helped arrange a House Resources Committee hearing on this issue where we offered testimony. In September we were in the capital supporting our Gulf coast brethren as they made their post-Katrina needs known to Congress and for the launch of the new Shellfish Caucus in the House of Representatives. We also visited key Congressional offices emphasizing repeal of the Byrd Amendment that has resulted in tariffs on American oysters exported to Canada. Finally, in December we attended a Pentagon briefing for the head of the Army Corps of Engineers to try and derail their march toward regulation of shellfish culture under provisions of the Clean Water Act. All of the issues above are still active and will be discussed in modest detail, along with some suggestions for actions that can be taken to keep the shellfish industry viable and growing.

QUAHOG (*MERCENARIA MERCENARIA*) SPAWNER SANCTUARIES: DOES SIZE OR LOCATION MATTER? Michael A. Rice, Department of Fisheries, Animal & Veterinary Science, University of Rhode Island, Kingston, RI 02879

Although the State of Rhode Island has undertaken projects since 1954 to relay quahogs (*Mercenaria mercenaria*) from pollution closure areas, many have argued that the numerous coves and inlets around Narragansett Bay that serve as a source of relay stock do in fact serve as *de facto* spawner sanctuaries. Adult qua-

hog densities in pollution closure areas have been reported to average as high as 190 individuals/m², but population densities above 40 individuals/m² in the coves and other shellfishery closure areas are not unusual in Narragansett Bay. Several lines of evidence suggest that high density adult populations of quahogs in closure areas may be reproductively impaired and thus limiting their utility as spawner sanctuaries that replenish nearby shellfisheries. First, shell growth of quahogs in coves has been shown to be impaired, presumably due to crowding effects, and it is known that crowding affects soft tissue growth, including gonads, *before* shell growth depression in many bivalves. Second, data from Greenwich Bay show a gradient of quahog larval abundance higher in the open areas of the bay with adjacent coves nearly devoid of larvae throughout an entire spring-summer monitoring season. For example, in the middle of Greenwich Bay in 1993 peak larval abundance was in mid-June reaching 170 larvae/L, but in Apponaug Cove and Greenwich Cove that have high density adult assemblages >40 individuals/m², a late July increase in larval numbers only reached a peak of 30 larvae/L. Subsequent data from the spring to fall of 1995 showed a down-Narragansett Bay gradient in mean seasonal quahog larval concentrations of 10.6, 16.0, 7.8, 5.4 and 3.6 larvae/L at Conimicut Point, Rocky Point, Warwick Point, Mount View/High Banks, and Wickford, respectively, with peak larval abundance on June 20 of 149.7 larvae/L and 197.4 larvae/L at Conimicut Point and Rocky Point, respectively. Collectively these data suggest that the quahog population in the large shellfishery pollution closure area in the Providence River and Upper Narragansett Bay may be the major source of larvae for much of Narragansett Bay, including Greenwich Bay. Third, recent 2005 data show that the condition index (CI) of quahogs from areas of high density, including Greenwich and Apponaug Coves, as well as the Providence River, to be substantially lower than in quahogs from areas that are actively fished, particularly the major conditional fishing areas in Upper Narragansett Bay. This growing body of evidence suggests that shellfishery pollution closure areas, especially in confined cove areas, may not necessarily serve well as *de facto* spawner sanctuaries. Partial harvest and relay of adult quahogs from the coves to managed sanctuary areas may be a good management alternative to increase overall spawning potential and subsequent quahog fishery recruitment.

AN INVESTIGATION OF CILIATE XENOMAS IN *CRASSOSTREA VIRGINICA*. Emily Scarpa and Susan Ford, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences Rutgers University, Port Norris, NJ 08349; Bruce Smith, New Hampshire Fish & Game, Durham, New Hampshire 03824; David Bushek, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, Port Norris, NJ 08349

Since the late 1990s, unusually high prevalences of xenomas have been noted during routine histological examination of oysters from Great Bay, New Hampshire. Xenomas are formed when in-

tracellular parasites accumulate within host cells, causing them to hypertrophy. Although in fish xenomas are commonly caused by microsporidians, in oysters xenomas are caused by ciliates, genus *Sphenophrya*, and are rare. Because they are macroscopically visible on gills, the marketability of infected oysters has been questioned.

In this study, samples were collected every fall from 1997 through 2005 and processed using normal histological procedures. In 2005, counts were also made of macroscopically visible xenomas. Prevalence varied according to site within Great Bay and also by year. In histological sections, it has increased notably since 1997, when only 1% of oysters were affected. In 2004, prevalence ranged from 33% to 82% between sites. Densities were mostly below 20 xenomas per histological section, but reached as high as 173. Macroscopically, samples from 2005 contained a mean 15.5 xenomas per oyster, ranging from 0 to more than 100.

The xenomas were located in gill water tubes and were often large enough to occupy the entire cross sectional area. They cause localized epithelial erosion and most likely impede water flow. Nevertheless, the histological appearance of the remaining tissues was not obviously affected and there was no clear correlation between oyster size and infection. There was an inverse relationship between the prevalence of *Haplosporidium nelsoni* (MSX) infections and that of xenomas, although the reason is presently unclear.

STRATEGY FOR DETERMINING BIOCHEMICAL NUTRITION OF SHELLFISH BROODSTOCK CONDITIONING. Ghazala Siddiqui,¹ Mark S. Dixon,² Joseph Choromanski,² David J. Veilleux,² and Gary H. Wikfors,² ¹Centre of Excellence in Marine Biology, University of Karachi, Karachi-75270, Pakistan; ²USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

The natural gametogenic cycle in oysters is closely associated with glycogen storage and subsequent synthesis of lipid during vitellogenesis. The lipid constituent of the egg is most affected by the quality of food provided to the broodstock and, thus, the deficiencies in essential fatty acids can alter fecundity and hatching rates and can trigger anomalies in the larvae. The importance of lipid and PUFA particularly docosahexonic acid (DHA; 22:6 *n*-3), eicosapentanoic acid (EPA; 22:5 *n*-3) and arachidonic acid (AA; 20:4 *n*-6) and sterols, 24-methylcholesterol or 24-methylenecholesterol, during egg and larval development have been recognized. Therefore, techniques have been employed to directly deliver or supplement the microalgal diets with these essential lipids used for broodstock conditioning.

The objective of this study is to evaluate the impact of fatty acid composition and sterol content of the algal diet on the fecundity, egg quality, hatching success and larval performance of *Crassostrea virginica* broodstock. For an initial experiment, the oysters

will be conditioned with unialgal diets of *Tetraselmis chui* and *Chaetoceros neogracile* and mixed diet of *T. chui* and *C. neogracile* (1:1, on dry weight basis). The fatty acid and sterol composition of these diets have previously been determined. Subsequently, an attempt will also be made to condition the oysters with diet supplemented with DHA, AA and sterols individually to confirm any specific requirements suggested by correlations found in the mixed-algal diet experiment.

A PORTABLE, EXPERIMENTAL SHELLFISH-FEEDING SYSTEM: DESIGN AND VALIDATION OF OPERATION.

Barry C. Smith,¹ Hélène Hégaret,² Sebastian Saliou,³ and Gary H. Wikfors.¹ ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Department of Marine Sciences, University of Connecticut, Groton, CT 06340; ³Pâtisseries Gourmandes SA, 22602 Loudeac Cedex, France

Environmental events, such as harmful algae blooms (HABs), typically do not occur at experimental research laboratories. Investigators are challenged to find ways to either bring the bloom or other environmental condition to the laboratory, or bring the experiments to the location of the given event. Compounding experimental location constraints, the duration of natural events can be very short. To address these realities, a water-exposure and phytoplankton-feeding system has been developed that is transportable to any location and can accommodate a variety of test organisms. Further, the system is readily adaptable to a variety of applications and experiment designs, from comparing responses of animals exposed to particulate and dissolved substances in seawater to conducting feeding studies with different phytoplankton suspensions.

A shipping tote forms the main structure of the exposure system. When set up for operation, twelve exposure trays reside inside the tote. Controlled water or culture flow is delivered to these trays through a bank of regulated flow meters. The original design supplied the flow meters with natural phytoplankton at ambient concentration, twice ambient concentration, and 0.2 μm -filtered bay-water using a peristaltic pump and tangential-flow filter. By re-plumbing the four manifolds, other combinations of liquids can be metered to the exposure trays; an example was an experiment exposing shellfish to four different algal sources in four head jars delivered to the trays by gravity feed. The system has repeatedly performed reliably, within flow-rate tolerances, with a variety of plumbed arrangements, on two continents. Although validated with Eastern oysters (*Crassostrea virginica*), Suminoe oysters (*C. ariakensis*), and bay scallops (*Argopecten irradians*), any organism that can fit in the exposure trays could be used as a test subject. The controlled-flow regime also allows post-exposure treatment of water and organisms for quarantine. The system components pack into the shipping tote itself for secure shipment to any destination.

A DEVICE FOR CONCENTRATING DINOFLAGELLATE CYSTS FROM SEDIMENT SAMPLES. **Barry C. Smith¹, Agneta Persson² and Gary H Wikfors.¹** ¹ USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Smedjebacksvägen 13, SE-771 90 Ludvika, Sweden

Finding and enumerating protistan cysts from sediment in the natural environment is a tedious and time-consuming endeavor, generally involving sieving of large quantities of sediment and long hours of microscope searching. With increasing concern about harmful algal blooms (HABs), and the fate of the cysts produced at the later part of the bloom, development of improved methods to detect, enumerate, and determine viability of cysts is of increasing importance. Separating other sediment components would facilitate cyst identification and counting by concentrating them and removing obscuring debris. A system to mechanically concentrate cysts, undamaged, from the natural environment has been developed and tested. The system allows for quantifiable recovery of natural cysts for a variety of uses.

The "Particle Separator" is a rectangular trough with an inclined screen slanting up the long dimension. A sediment sample is suspended in water and delivered to the deep end of the trough by a peristaltic pump, and the suspension is circulated between a reservoir and the trough until all particles have settled. Each particle present has a unique combination of mass, volume, and surface coefficient of friction. Thus, similar particles will settle onto the screen at discrete locations along the length of the trough. Cysts are recovered from the section of the screen where they have accumulated. The system has been used to collect, identify, and quantify cysts from two locations. Further, a bivalve feeding study using natural dinoflagellate cysts has been conducted with cysts collected and concentrated from a sediment sample.

EVALUATION OF SCALLOP GENETIC LINES FOR GROWTH, OVERWINTERING SURVIVAL AND PHENOTYPIC AND GENOTYPIC MARKERS. **Sheila Stiles, Joseph Choromanski, Dorothy Jeffress, Steven Pitchford and Dionna Williams.** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

One of the major obstacles to bay scallop commercialization in the northeast US is overwintering survival. To address this issue, genetic lines of bay scallops, *Argopecten irradians*, are being selectively bred for improved growth and survival. One strategy is to increase growth rate to reach a marketable size prior to the onset of winter, thus bypassing the need to overwinter. Another approach is to select scallops for improved over-winter survival where temperatures often reach 0°C. A preliminary trial to assess overwintering survival from December to March of various bay scallop genetic lines of different sizes and ages in tanks with ambient flowing seawater resulted in survival ranging from 8.3%

to 45.5% in 2005. Lines were composed of F_1 and F_2 generation groups, selected primarily for growth, a self-fertilized inbred line, and lines with different phenotypic markers such as striped shells, which should reflect differences in genotypes. Mean sizes of scallops from all groups ranged from 15.68 mm to 48.84 mm. The highest percentage survival was in a low selected line with slower growth. This outcome suggests an inverse relationship between growth rate and survival. The next highest percent survival was in the inbred line, which could indicate that some inbred lines are better adapted than other groups for specific traits under certain conditions. More focused experiments are warranted to confirm these preliminary observations.

OYSTER SET IN LONG ISLAND SOUND FOR CONNECTICUT (1997–2005). Inke Sunila, State of Connecticut, Department of Agriculture, Bureau of Aquaculture, P.O. Box 97, Milford, CT 06460

Long Island Sound is a major growing area for eastern oysters, *Crassostrea virginica*. In Connecticut, oyster aquaculture is based on leased grounds, where oyster seed from natural seed beds is transplanted for grow-out. Only a small portion of oysters originate from hatchery-raised seed. Thus, a steady annual oyster set would result in a steady production of market oysters. However, commercial oyster set in CT occurs irregularly and often with intervals of several years, unlike in more southern estuaries. A major set in 1987 resulted in peak production during the following years and in 1995 Long Island Sound accounted for 94% of all cultured oysters in the eastern US.

Each fall the Bureau of Aquaculture collects oysters from the entire CT shoreline. One of the parameters measured is the set on oyster shells. During the fall survey the set from the previous summer is already visible to the naked eye. An average of 45 sites and 1370 shells are checked for the presence of set each year.

In 1997 and 1998 an epizootic of *Haplosporidium nelsoni* (MSX) affected CT's oyster stocks. MSX characteristically infects market size oysters first and seed in its second year. There was a heavy set in 1997, but the seed acquired MSX infection the next year. 1998 was also a year of relatively good oyster set, but the seed became infected as well. No significant oyster sets occurred during the following five years. Patchy sets were observed in some areas of no major commercial interest. Production decreased steadily because market size oysters decreased without further recruitment.

In 2004 a significant set occurred. It was a light set with on the average of only 15% of the shells surveyed set on. However, it landed in CT's major oyster growing areas south of Bridgeport, Norwalk and Westport. A good set also occurred in 2005, but mostly in the Milford-Branford area. No oyster set has been observed during the study years in the eastern end of the state between Clinton and Stonington. At the present time, oysters originating from the 2004 set have no significant disease prevalences.

Oysters originating from natural set need three to four years to reach market size. Without interference from a disease outbreak they are likely to form a new peak in CT's oyster production after a couple of years.

BIOCHEMICAL COMPOSITION AND ADDUCTOR MUSCLE CELL SIZE OF TRIPLOID AND DIPLOID BAY SCALLOPS, *ARGOPECTEN IRRADIANS*. Amandine Surier, Martha's Vineyard Shellfish Group, Oak Bluffs, MA 02557; Chester B. Zarnoch, Aquatic Research and Environmental Assessment Center, Brooklyn College, Brooklyn NY 11210

Triploidy which has been found to improve overall performance in many shellfish, is particularly interesting in scallops as the increased growth rate is associated with decreased gonad development and increased adductor muscle mass. Triploid's increase in somatic biomass is thought to be the result of energy reallocation from reproduction towards somatic growth or increased fitness due to higher heterozygosity. Another hypothesis is triploidy gigantism, which associates the increased size of triploid organisms with a larger cell size.

In July 2003, under funding from the Northeastern Regional Aquaculture Center, triploidy was induced in the bay scallop, *Argopecten irradians*. The experimental scallops, which tested 97% triploid in July 2004, were grown in bottom cages in Katama Bay, Massachusetts. Triploid wet adductor muscle indexes were 52% and 17% greater than diploids in July and October 2003 respectively.

In December 2003, triploid and diploid adductor muscle samples were sent to Brooklyn College for biochemical composition. Although the protein and carbohydrate contents were higher and lipid content was lower in triploid muscles the differences were not significant. In the spring 2004, survivors from the experiment were sampled for cell size analysis. A portion of the smooth adductor muscle from triploids and diploids was processed using standard histological techniques, photographed and analyzed for muscle cell size and number of cells/area using NIH ImageJ software. Adductor smooth muscle fibers of triploids were significantly wider than those of diploid controls. In contrast the number of muscle fibers per unit area was not significantly different between ploidy groups.

ASSESSING IMPACTS OF SHELLFISH AQUACULTURE ON EELGRASS POPULATIONS IN EASTERN LONG ISLAND SOUND. Jamie Vaudrey,¹ Tessa S. Getchis,² Robert Britton² and Jim Kremer.¹ ¹University of Connecticut, 1080 Shennecossett Road, Groton, CT 06340; ²Sea Grant Extension Program, 1080 Shennecossett Road, Groton, CT 06340

Eelgrass (*Zostera marina*) is the dominant vascular plant of northern estuaries of the east and west coasts of the United States. Eelgrass beds provide critical ecological functions such as remov-

ing excess nitrates and phosphates and stabilizing fine sediments. Beds also provide critical habitat to a myriad of marine organisms including juvenile fish, shellfish, and crustaceans, among others. Eelgrass is considered an indicator of a “healthy” system and much attention has been focused on investigating potential causes of the loss of eelgrass and determining methods to minimize the decline in eelgrass abundance.

Bivalve aquaculture, specifically the utilization of submerged cultivation and depuration gear has been implicated as a potential source of negative impacts to eelgrass populations. However, shellfish aquaculture has also been shown to provide an equivalent or greater degree of ecosystem services as submerged aquatic vegetation.

This study was conducted to determine the type and degree of impacts and benefits that oyster depuration bottom cages have on eelgrass and surrounding water and sediment quality in order to provide producers and policy-makers with the scientific data needed to make informed decisions regarding the siting of aquaculture in Long Island Sound. Effects of the oyster cages were gauged by looking at reference sites (eelgrass areas without cages, bare areas with cages) and experimental plots (eelgrass areas with cages) in triplicate. Direct effects measured included: short shoot density, dry weight areal biomass, and growth rate. Indirect effects measured using water column and sediment samples included: benthic microalgae chlorophyll concentration, sediment percent organics, and water column chlorophyll concentrations. Water column profile measurements were recorded at all sites on the cage deployment and retrieval days (temperature, salinity, dissolved oxygen, turbidity, *in situ* chlorophyll). Video monitoring was utilized to document physical disturbance from the cultivation gear.

The water column at all three sites was vertically well mixed and no effect of the cages on water column characteristics was detectable. Sediment characteristics did not change as a result of the presence of the cages over the 2–3 week deployments. One deployment showed a statistically significant increase in sheath length at the eelgrass with cages site, indicating that the eelgrass was exhibiting either a stress response to reduced light availability or an increase in production due to higher nutrient availability in the pore waters of the sediment. Further deployments are needed to verify this response and determine the cause for the increase in sheath length. No other eelgrass indices showed a significant effect of the cages.

COMMUNAL EFFECTS AMONG *ARGOPECTEN IRRADIANS*, *LITTORINA LITTOREA*, AND *ILYANASSA OBSOLETA*. David J. Veillenx,¹ Sean Grace,² Ronald Goldberg,¹ and Dwight Smith.² ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT, 06460; ²Southern Connecticut State University, 501 Crescent St., New Haven, CT

In an attempt to investigate ways to control biofouling and sedimentation associated with aquaculture gear, two species of snail, *Littorina littorea* L. and *Ilyanassa obsoleta* Say, were added to bay scallops, *Argopecten irradians* Lamarck, being cultured in pearl nets (N = 15). The study site was in Milford Harbor, at the dock of the National Marine Fisheries Service, Milford Laboratory. The study was conducted over forty days, from June 29, 2004, to August 8, 2004. The total amount of fouling (as determined by weight), total growth of scallops and snails (as a measure of shell height and buoyant weight), sedimentation, mortality, and flow rate through the nets were analyzed. Results indicated that although there was no significant difference in amount of fouling, sedimentation, flow, and mortality associated with the snail treatments, there was a significant increase in the growth rate of scallops.

SUPERIOR GROWTH OF TRIPLOID EASTERN OYSTER DEPENDS ON CULTURE ENVIRONMENT. Yongping Wang,¹ Ximing Guo,¹ Gregory DeBrosse,¹ Rick Karney,² Paul Bagnall,³ Jack Blake,⁴ Susan Ford¹ and David Bushek.¹

¹Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, Port Norris, NJ 08349;

²Martha's Vineyard Shellfish Group Inc., Oak Bluffs, MA 02557;

³Edgartown Shellfish Department, Edgartown, MA 02539; ⁴Sweet Neck Farm, Edgartown, MA 02539

The eastern oyster (*Crassostrea virginica*) faces three major diseases in the Northeastern region: MSX (caused by the parasite *Haplosporidium nelsoni*), Dermo (caused by the parasite *Perkinsus marinus*), and the juvenile oyster disease (JOD, caused by a bacterium). The development of a disease-resistant and fast growing stock would help the oyster culture industry. In a previous study, we have shown that hybrids between the Rutgers NEH strain (resistant to MSX and Dermo) and a commercial stock from the Flower's Oyster Company (FMF, known for its fast growth and JOD-resistance) outperformed either parental stock in yield under Dermo infections. To see if the hybrid advantage can be transferred to or amplified in triploids (3n) which grow faster than diploids (2n), we produced 3n hybrids between the two stocks and compared them to 2n hybrids, pure-line 2n and 3n controls. Four groups were produced in the summer of 2005: 1) 3nFN, 3n hybrids by crossing 2n FMF females and 4n NEH males; 2) 3nNN, 3n NEH by crossing 2n and 4n NEH; 3) 2nFN, 2n hybrids between 2n FMF females and 2n NEH males; and 4) 2nNN, 2n pure NEH control. The four groups were deployed at Cape Shore (CS) in New Jersey and two sites at Martha's Vineyard in Massachusetts: one in Katama Bay (KB) and the other in a hatchery at Edgartown Harbor (EH). Oyster spat were produced inside the hatchery using sterilized seawater and certified Dermo- and MSX-free before deployment at the two MA sites. At 3–4 months of age, 50–100 oysters were sampled from each group. Ploidy of each oyster was individually verified using flow cytometry and all three 3n groups

were 100% triploid. Triploids and diploids were compared in pairs between 3nNN and 2nNN, and between 3nFN and 2nFN. Growth at the KB site was significantly faster than the other two sites. Overall, the oysters were 24.7 mm in height at KB, 13.2 mm at EH and 12.6 mm at CS. Triploids were bigger than diploids at all sites, although the magnitude of difference varied considerably among sites. At the slow-growing sites (CS and EH), triploids were larger than diploids by 11–18% in shell height and 30–66% in whole body weight. At the fast-growing site (KB), triploids were strikingly larger than diploids—by 49–50% in shell height and 165–180% in whole body weight. This result demonstrates that superior growth in triploids depends on the culture environment. Triploids, when cultured in productive waters and systems, will bring considerable benefits to oyster farmers. The fact that triploids grow significantly faster than diploids at 4 months of age, long before sexual maturation, suggests that sterility is not an important factor contributing to the superior growth of triploids. The superior growth of triploids is likely caused by triploid gigantism, whose expression is dependent on culture environments. Triploids at KB also had fewer deaths from JOD than diploids.

A COMPARISON OF BAY SCALLOP, *ARGOPECTEN IRRADIANS*, SURVIVAL AND GROWTH WHEN FED *TETRASELMIS CHUI* GROWN IN E OR F MEDIA. James C. Widman Jr., Shannon L. Meseck, David J. Veilleux and Mark S. Dixon. USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford CT 06460

Bay scallops, *Argopecten irradians*, were fed *Tetraselmis chui* grown in either E or f media. Phytoplankton concentrations were maintained at 8,000 cells/ml utilizing an automated computer control system. On a daily basis buckets were drained and filled with 15 L of 1 μ cartridge filtered seawater. Twice weekly, scallops were removed from the containers and placed in clean 15 L buckets. Shell height measurements were recorded weekly.

Scallop survival averaged 98% for both groups. There was no difference in survival of scallops fed *Tetraselmis chui* grown in either E or f media.

Urea concentrations after 24 hours were markedly different from one another. Urea ranged from 0.28–0.31 μ mol/L after 24 hours in scallops fed *Tetraselmis chui* grown in f media. Scallops fed *T. chui* grown in E media had urea concentrations ranging from 4.58–4.73 μ mol/L during the same time period.

Scallops fed *Tetraselmis chui* with an initial mean shell height of 7.9–8.0 mm grew to final mean shell heights of 12.3–13.5 mm 26 days later. Survival was high for scallops fed *Tetraselmis chui* grown with either type of media. After 26 days there were no significant differences ($p > 0.05$) between scallops fed *T. chui* grown on either E or f media.

DO VARYING *TETRASELMIS CHUI* CONCENTRATIONS AFFECT AMMONIA CONCENTRATIONS IN BAY SCALLOP, *ARGOPECTEN IRRADIANS*, CULTURES? James C. Widman Jr., Shannon L. Meseck, David J. Veilleux and Mark S. Dixon. USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford CT 06460

Bay scallops, *Argopecten irradians*, were grown in semi-static culture systems containing *Tetraselmis chui* at concentrations of 1,000, 3,500, 8,000 and 11,000 cells/ml. We wanted to determine whether phytoplankton concentrations would affect ammonia levels in the culture system. F media was used to grow the *Tetraselmis chui*. Microalgal cell concentrations were continuously monitored and maintained by an automated computer control system. Buckets were drained and filled with 15 L of 1 μ cartridge filtered seawater daily. Twice weekly scallops were removed from the containers and placed in clean 15 L buckets. Every week ammonia levels were measured over a 24 hour period.

Scallops grew from initial mean shell heights of 10.5–10.9 mm to final mean shell heights of 15.2–17.9 mm. Scallops grew at similar rates for the first 14 days. After 21 days, scallops grown at a cell concentration of 11,000 cells/ml were significantly smaller than those grown at 1,000 cells/ml. Throughout the experiment scallops grown at 1,000 and 3,500 cells/ml were not significantly different ($p > 0.05$) from one another. Similarly, scallops grown at 3,500 and 8,000 cells/ml grew at similar rates ($p > 0.05$). Scallops grown at the two highest concentrations, 8,000 and 11,000 cells/ml grew at similar rates ($p > 0.05$). A previous study had shown no growth differences when scallops were fed varying concentrations of *T. chui* grown in E media.

Ammonia concentrations were not measured above 10 μ mol/L. There was no relationship between the ammonia concentrations observed and scallop growth rates.

In summary, ammonia levels were not affected by phytoplankton concentrations. Scallop growth was affected by phytoplankton concentration of *Tetraselmis chui* grown with f media.

IMMUNE-STATUS ASSESSMENTS OF OYSTERS FROM THE 2004 ANNUAL STATE OF CONNECTICUT BUREAU OF AQUACULTURE SURVEY. Gary H. Wikfors,¹ Inke Sunila,² Jennifer H. Alix,¹ April N. Croxton,¹ H       H      ,³ and Shannon L. Meseck,¹ ¹USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Bureau of Aquaculture, Department of Agriculture, State of Connecticut, Milford, CT 06460; ³Department of Marine Sciences, UCONN, Groton, CT 06430

Every organism has a defense mechanism. When the capacity of the defense mechanism is exceeded, pathological changes follow. The State of Connecticut Bureau of Aquaculture has been conducting an annual autumn survey of oyster pathology for several years; the 2004 survey provided an opportunity to explore

possible relationships between pathology observed histologically and hemocyte immune-defense measurements made with flow-cytometry. Ten oysters from each of 14 sites selected from the survey were sampled for hemolymph and analyzed individually for descriptive hematology (numbers and percentages of different hemocyte types, percentage of dead hemocytes) and several immune functions (phagocytosis, respiratory burst, adhesion). Hemocyte parameters and histological findings were compared on an individual-oyster basis using multivariate statistics.

The strongest associations of hemocyte parameters were with intensity of parasitism by *Perkinsus marinus* (Dermo disease), as measured by the Mackin scale. Oysters with slight infestations (Mackin 0.5–1) had elevated granulocyte percentages and functions (phagocytosis, respiratory burst); whereas, circulating granulocytes and their functions were repressed with more-severe Dermo disease (Mackin 2 and above). These findings are consistent with the etiology of Dermo disease described previously: the initial stimulation of hemocyte functions represents induction of the defense mechanism to the parasite, and subsequent development of pathological changes accompanies exceedance of the defense mechanism. Other associations between pathology and hemocyte characteristics were less pronounced than those for Dermo because many oysters showed multiple pathologies, but several observations suggest possible future research topics, relative to immune status and pathology in oysters.

LISTING A SPECIES AS THREATENED OR ENDANGERED—WHAT HAPPENED WITH THE EASTERN OYSTER PETITION? Gary H. Wikfors, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

A petition to consider the listing of the Eastern Oyster, *Crassostrea virginica*, as threatened or endangered pursuant to the Federal Endangered Species Act (ESA) was filed by Ecosystem Initiatives Advisory Services in January 2005. A positive initial finding (90 day finding), based upon evidence presented in the petition and existing information in possession of the NOAA ESA Program at the time of petition receipt, prompted creation of a Biological Review Team (BRT), consisting of representatives of NOAA and state resource agencies from throughout the US range of the species, to assess the status of the species. The process for determining whether a species should be listed is based upon the best available scientific and commercial information. The Status Review Report (SRR) is based upon an assessment of factors specified in section 4(a)(1) of the ESA that may be contributing to decline, including: 1) the present or threatened destruction, modification, or curtailment of its habitat or range; 2) overutilization for commercial, recreational, scientific, or educational purposes; 3) disease or predation; 4) inadequacy of existing regulatory mechanisms; or 5) other natural or manmade factors affecting the con-

tinued existence of the species. Finally, risk-of-extinction analysis must be completed by the BRT.

Sources of data that the BRT explored in the SRR included published scientific literature, presentations by invited experts, fishery and fishery-independent population assessments housed in various state and federal repositories, and a survey of state resource managers and academic experts from each coastal state within the species' range. The document will be peer reviewed, and as such, the SRR will represent the most comprehensive resource document for this species. The SRR will be completed, despite withdrawal of the petition prior to the decision date, thus, it is hoped that it will help inform coastal resource managers as they continue to manage and restore this species.

INVESTIGATING THE OVER-WINTER MORTALITY OF HARD CLAM SEED, *MERCENARIA MERCENARIA*. Chester B. Zarnoch and Martin P. Schreihman, Aquatic Research and Environmental Assessment Center (AREAC), Brooklyn College, The City University of New York, 2900 Bedford Ave., Brooklyn, NY 11210

Over-winter mortality of aquacultured hard clam seed is a significant problem for Mid-Atlantic and Northeast aquaculturists. Although protecting seed from predators improves survival, significant mortalities still frequently exceed 50%. This is often attributed to the severe temperatures of winter; however, this hypothesis has yet to be systematically investigated. We hypothesize that extended periods of low water temperature ($<5^{\circ}\text{C}$) will result in reduced hard clam pumping, and thus an increase in the use of energy stores for metabolism. This would lead to an insult in physiological condition and cause mortality in the spring when water temperatures increase, food levels are low and metabolic demands are high.

In this study, seed (SL = 10 mm) were planted at two sites in Jamaica Bay, NY in the fall of each year between 2001–2004, to investigate the magnitude of over-winter mortality and to study physiological condition through the winter and spring. The data indicate that a mild winter results in negligible mortality. Similarly, a severe winter followed by a spring in which the rise in water temperature coincides with high food levels also results in low mortality. In contrast, significant mortality (up to 45% per sample) occurs in the spring following a severe winter, at a time when water temperatures are rising and food levels are low ($<3\mu\text{g/L}$). During this period a rapid decline of carbohydrate content is observed, suggesting the use of energy reserves to maintain increased metabolic activity. Mortality occurs when carbohydrate levels fall below 10% of the tissue dry weight. Therefore, the timing of phytoplankton blooms and the increase in water temperature during the spring dictates the magnitude of over-winter mortality following a severe winter.

ABSTRACTS OF TECHNICAL PAPERS OF THE JUVENILE OYSTER DISEASE SESSION

February 27–March 1, 2006

A REVIEW OF BACTERIOLOGICAL STUDIES SUPPORTING *ROSEOVARIUS CRASSOSTREAE* AS THE ETIOLOGICAL AGENT OF JUVENILE OYSTER DISEASE IN *CRASSOSTREA VIRGINICA*. Katherine J. Boettcher^{1,2} and Aaron P. Maloy.^{1,3} ¹Department of Biochemistry, Microbiology, and Molecular Biology, University of Maine, Orono, ME. 04469-5735. ²Present address: 11208 Beechwood Pointe, Smithfield, VA 23430. ³Present address: U.S. Geological Survey, Lake Ontario Biological Station, Oswego, NY 13126

By 1997, studies by other investigators had provided evidence for either a protistan or bacterial etiology for JOD. That year we conducted a study on Maine's Damariscotta River to distinguish between these two possibilities. Both a delay in JOD-onset and a significant reduction in cumulative mortalities were observed among oysters exposed to strictly antibacterial agents. In addition, there was a numerical dominance of a novel species of marine alpha-*Proteobacteria* in JOD-affected oysters. By the end of the recovery period, the levels of these bacteria in the survivors had dropped to <1% of total colonies. This species (named *Roseovarius crassostreae*) was subsequently found to be consistently and exclusively associated with JOD throughout the Northeast. Heavy colonization by *R. crassostreae* was also documented among a population of larger oysters with JOD-signs that were in otherwise good condition. Such observations argue against a role for *R. crassostreae* as a non-specific colonizer of terminally ill individuals. An attempt to reproduce JOD by exposure to *R. crassostreae* resulted in impaired feeding of challenged oysters, followed by mortality episodes during which the inoculating strain was reisolated from affected individuals. A later attempt to produce the entire suite of JOD-signs resulted in increased levels of conchiolin deposition among challenged animals (although without subsequent mortality). Finally, the presence of *R. crassostreae* was confirmed in a field population from Massachusetts one week prior to the appearance of gross signs and ensuing mortality. The cumulative evidence will be discussed within the current guidelines for proof of causation (e.g. Koch's postulates).

A REVIEW OF MOLECULAR APPROACHES FOR EPIZOOTIOLOGICAL STUDIES OF JUVENILE OYSTER DISEASE AND DETECTION OF *ROSEOVARIUS CRASSOSTREAE* IN SITU. Katherine J. Boettcher^{1,2} and Aaron P. Maloy.^{1,3} ¹Department of Biochemistry, Microbiology, and Molecular Biology, University of Maine, Orono, ME. 04469-5735. ²Present address: 11208 Beechwood Pointe, Smithfield, VA

23430. ³Present address: U.S. Geological Survey, Lake Ontario Biological Station, Oswego, NY 13126

We sought to develop genetic tools for the culture-independent detection of *Roseovarius crassostreae* and for understanding range expansion of JOD. Greater than 99.8% identity was found among the 16S rDNAs of isolates, but informative variation was detected within the 16S-23S rDNA internal transcribed spacer (ITS). Using restriction enzyme analysis and sequencing of the ITS region, a total of 11 genotypes were identified. In many instances, a single genotype was recovered from a given epizootic, but occasionally multiple genotypes were involved. Furthermore, phylogenetic analysis showed that diversification of the ITS did not map directly onto patterns of disease occurrence. Still, most genotypes were associated with specific years and/or locations. The data are consistent with the existence of indigenous *R. crassostreae* that become enriched at sites of oyster culture. A PCR assay was also developed for the direct detection of *R. crassostreae* from oysters. The assay was validated using closely related roseobacters, and no false positives were obtained from oyster samples. The assay has the potential to detect as few as 10 cells of *R. crassostreae* in oysters, and is equally or more effective than standard bacteriology in detecting the bacterium from field samples. Finally, in related studies we had shown bacterial microcolonies on the inner shell surfaces of oysters with JOD. To confirm that the bacteria were *R. crassostreae*, we used universal primers to produce a library of 16S rDNA clones from affected individuals. Sequence analyses confirmed the numerical dominance of *R. crassostreae* sequences and no other species was similarly abundant.

JUVENILE OYSTER DISEASE: MICROFLORA FROM CONTROL AND INFECTED POPULATIONS OF AMERICAN OYSTERS (*CRASSOSTREA VIRGINICA*) ALONG THE ATLANTIC COAST. Rocco C. Cipriano,¹ E. Jay Lewis² and Ana Baya.³ ¹United States Geological Survey, National Fish Health Research Laboratory, 11649 Leetown Road, Kearneysville, WV 25430; ²NOAA/NOS, Coastal Center for Environmental Health and Biomolecular Research, 904 South Morris Street, Oxford, Maryland 21654; ³University of Maryland, College of Veterinary Medicine and Maryland Department of Agriculture, 8077 Greenmead Drive, College Park, MD 20742

The bacterial flora was evaluated from 11 populations of the American oysters (*Crassostrea virginica*) cultured in Virginia, New York, Massachusetts, Rhode Island, and Maine. Samples were obtained from both diseased and apparently unaffected oysters. The prevalence of juvenile oyster disease was based on mortality within a population and clinical signs of infection on individual oysters. Bacterial swabs were obtained from clinical internal surfaces with evident mantle recession, blackening, and conchiolin. Similar samples were obtained from the internal surfaces of shells from individuals that did not show clinical evidence of infection. Swabs were eluted (weight to volume) in sterile phos-

phate buffered saline and bacteria were cultured by dilution plate counts on medium containing 2.5% sea salts, 0.1% NH_4Cl , 0.02% Na acetate, 0.03% peptone, 0.01% yeast extract, and 1.5% agar. When the results of the 11 sample sites were reviewed collectively, bacterial counts ranged between 1.0×10^6 to 4.1×10^9 colony forming units (cfu) per mL of sample. Motile aeromonads, pseudomonads, streptococci, *Comomonas terrigena*, *Acinetobacter* sp., and *Vibrio* spp. were commonly isolated. Because of their prevalence in both affected and non-affected oysters, none of the aforementioned organisms were considered putative etiologic agents. Even the vibrio isolates were obtained at nearly the same frequencies from infected and normal oysters. A total of 18 known vibrio species, as well as 26 unidentified species of vibrios, were obtained. Of these, *Vibrio alginolyticus* (45%), *V. splendidus* (42%), and *V. pelagius* (41%) were the most prevalent species. Unidentified vibrios were isolated so infrequently that they were not considered to cause disease.

PATTERN, EFFECTS, AND REMEDIATION OF JUVENILE OYSTER DISEASE (JOD) IN THE DAMARISCOTTA RIVER ESTUARY, MAINE. Richard Cline, Dodge Cove Marine Farm, Inc., P.O. Box 211, Newcastle, Maine 04553

Roughly eighty percent of Maine's cultivated American oyster production is located in the Damariscotta River. Common nursery techniques are deployment of electrically powered floating upwellers (FLUPSYS) for hatchery raised 2–2.5 mm seed (May–June), and graded transfer of 12–15 mm seed into floating bags (July–October) for end of season dispersal on shallow sub tidal bottom at 30–45 mm. Salinities in the areas of densest culture range seasonally from 23–31 ppt. Temperature maxima in August approach 24–27°C, while winter minima, often under sea ice, can fall to –1.5°C. Oysters will be metabolically active from April–November although most shell growth occurs from June through September.

JOD probably appeared in 1991 or 1992 although the effects were mild at first and hard to discern from other causes of mortality. By 1993 mortalities of nursery raised seed had surpassed 50% and in subsequent years would range from 50–80% of the seed crop. Symptoms appeared from late July to early August and were characterized by a cessation of growth at the 12–20 mm size, an extreme cupping of the lower valve, heavy interior shell concholin deposits, a general loss of healthy pigmentation, and eventual gaping before death. Distribution of diseased oysters within the floating bag nursery was non-random predominately affecting smaller, slower growing juveniles, but also showing a “locus centered” pattern within bag lines where some bags were fully involved while others were only lightly involved.

Attempts at remediation of the epizootic by our company began piece-meal with trial and error tests of the following strategies:

1) Split hatchery seed purchases between May and August deliveries.

2) Adopt use of FLUPSYS for small seed nursery culture (window screen tray and bag inserts previously used).

3) Geographically separate the FLUPSYS nursery from the floating bag nursery and where possible, locate disease free sites for FLUPSYS.

4) Undertake a formal selective breeding program choosing fast growing disease challenged oysters as broodstock.

5) Avoid overcrowding juveniles in the nursery while maximizing seawater circulation through the FLUPSYS and floating bags.

6) Expose hatchery juveniles (2–2.5 mm) and FLUPSYS juveniles (10–15 mm) to microbial probiotic colonization with lab cultures of *Stappia stellulata*, naturally occurring marine bacteria isolated from inside shell and mantle surfaces of healthy juvenile American oysters.

Other Maine companies may have tried a combination of different remedial strategies about which we are unaware.

By 2001, the course of the disease had lessened perhaps as a result of our remediation or perhaps it had simply run its course. Since then our nursery juvenile mortality from all causes has diminished to under 5% and overall yields of harvestable oysters have risen to 44% of purchased hatchery seed.

A REVIEW OF JUVENILE OYSTER DISEASE (JOD) OUTBREAKS IN MAINE AND APPROACHES TAKEN TO REDUCE JOD INDUCED MORTALITIES. Christopher V. Davis, Pemaquid Oyster Company, Inc., P.O. 302, Waldoboro, ME 04572 and the Maine Aquaculture Innovation Center, 5717 Corbett Hall, Orono, ME 04469, Paul D. Rawson, School of Marine Sciences, University of Maine, Orono, ME 04469, Bruce J. Barber, Eckerd College, 200 54th Avenue South, St. Petersburg, Florida 33711, Robert O. Hawes, Professor *emeritus*, University of Maine, Orono, ME 04669 and Scott C. Feindel, School of Marine Sciences, University of Maine, Orono, ME 04469

Outbreaks of Juvenile Oyster Disease (JOD) have been an ongoing concern for growers of Eastern oysters (*Crassostrea virginica*) in the northeastern United States since JOD's first documented occurrence in 1988. In Maine, JOD induced mortalities have resulted in juvenile crop losses exceeding in some cases 90%. A collaboration of industry growers and University of Maine researchers has led to the development of genetically selected broodstock and specific management strategies to help alleviate JOD impacts on Maine oyster farmers. Since 1985, the University of Maine's oyster selective breeding program has produced multiple lines of second and third generation broodstock that exhibit superior growth and JOD resistance compared to unselected controls. Concurrently, studies relating size-dependency to rates of JOD induced mortality have led oyster farmers to develop management strategies that maximize growth prior to and following midsummer epizootic periods when high JOD induced mortalities tend to occur.

JOD INVESTIGATIONS BY RUTGERS AND SUNY, STONY BROOK, 1991-1994: EPIZOOTIOLOGY, HISTOPATHOLOGY AND BACTERIOLOGY. Susan Ford, Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349

In 1988, a producer in Maine sent a batch of juvenile oysters to the Haskin Shellfish Research Laboratory (HSRL) for pathological examination. The oysters had the classical symptoms of what would become known as Juvenile Oyster Disease (JOD)—the organic deposit on the inner shell—but no histologically detectable pathogen. Although this may have been the first recorded outbreak of JOD, concerted investigations of the disease did not begin until 1991, after extensive juvenile oyster mortalities occurred on Long Island, New York. That year, studies were conducted by HSRL and SUNY Stony Brook and by Battelle Ocean Sciences, at the Frank M. Flower Co. at Oyster Bay, NY, on the north shore of Long Island. They documented 1) the timing and extent of mortalities; 2) that they occurred at temperatures $\geq 21-22^{\circ}\text{C}$; 3) that reducing densities also reduced mortalities; and 4) that lesions, but no obvious pathogen, were detectable in the gills and mantle of affected oysters by either light or electron microscopy, although bacteria were observed on and within the deposit. This study also recorded a link between phytoplankton blooms and the occurrence of lesions. In 1992, a larger study was undertaken that involved 8 sequentially spawned cohorts deployed over a several-month period at sites in and offshore of Oyster Bay, and a separate series deployed at the Blue Points Hatchery on the south shore of Long Island. Wild set also developed JOD symptoms when exposed in Oyster Bay. Regardless of age or size, JOD symptoms and subsequent mortality began about the same time in all groups at Oyster Bay, but never appeared at Blue Points. Oysters >25 mm developed shell-deposit symptoms, but experienced low mortalities ($<30\%$) compared to smaller oysters in which losses were 60 to 90%. Histologically detected lesions on the mantle were highly correlated with shell deposits and mortality, and were present about 2 weeks before mortality began. Results offered the FMF Co. a means to control the disease: earlier hatchery production so that the oysters would be ≥ 25 mm when the “window” of exposure to the JOD agent(s) was present. At about this time, we became aware of research in France that implicated a marine bacterium in the genus *Vibrio* in Brown Ring Disease (BRD) of Manila clams. The BRD symptom, like that of JOD, is an organic deposit on the inner shell. Consequently, HSRL and SUNY Stony Brook embarked upon a third project in collaboration with the FMF Co. It was conducted in 1993–94 and focused on determining the role, if any, of *Vibrio* bacteria and of plankton blooms in JOD. Field sampling of three cohorts showed an exponential increase in total *Vibrio* counts just before the onset of JOD symptoms, and that the *Vibrio* increases were preceded by plankton blooms. Several *Vibrio* isolates were used in challenge experiments, and al-

though several caused mortality, none consistently reproduced the JOD shell deposit symptom. A final study was conducted in 1994 when Dr. Christine Paillard, the French investigator who discovered the cause of BRD in Manila clams spent several months at HSRL. She demonstrated that mantle fluid of affected oysters caused JOD symptoms when injected into the shell cavities of experimental oysters. She also isolated a number of bacterial species (genera *Vibrio*, *Aeromonas*, and *Pseudomonas*) that were systematically and predominantly present only in individuals with JOD symptoms. None, however, produced JOD symptoms in challenged oysters. The conclusion of these studies was that JOD was most likely caused by one or more bacterial species, perhaps associated with plankton blooms, which affected principally oysters in crowded culture situations and that outbreaks were probably triggered by temperature.

The Northeastern Regional Aquaculture Center funded most of this work.

TESTING DISEASE RESISTANCE IN OYSTERS: EXPERIMENTAL INFECTIONS WITH BACTERIAL PATHOGENS IN *CRASSOSTREA VIRGINICA* LARVAE AND SPAT. Javier Gómez-León, Luisa Villamil, Rachel Hadley and Marta Gómez-Chiarri, Department of Fisheries, Animal, and Veterinary Science, University of Rhode Island, 20A Woodward Hall, Kingston, RI 02881

Culture of the American oyster (*Crassostrea virginica*) is a traditional activity that has great economical importance in the East Coast of USA and the Gulf of Mexico. Globally, shellfish production is often affected by bacterial pathogens, mainly *Vibrios*, which lead to high mortality rates in shellfish hatcheries. Another bacterial disease that has heavily impacted oyster culture in the Northeast US is Juvenile Oyster Disease (JOD), thought to be caused by *Roseovarius crassostreae*. In the present study, bacterial isolates that caused important mortalities in Pacific oyster larvae, RE22 and RE101, as well as an isolate from JOD-affected oysters (CV919-312) were used to perform experimental infections of oyster larvae and spat in order to determine differences in the susceptibility to bacterial infection of three oyster lines: a local Rhode Island line, a line resistant to Dermo and MSX (NEH), and a line resistant to JOD (FMF). All bacterial isolates tested were able to induce significant mortality in larvae and spat of *C. virginica*, reaching mortalities ranging from 50–100%. Differences in susceptibility between the lines were observed, with the NEH line showing the highest survival. Infected larvae exhibited abnormal circular swimming movements on their sides and deformed velum with cilia clumping. Factors affecting survival included temperature and size of the oysters. This research may provide a useful tool to test for disease resistance mechanisms in oysters.

INVESTIGATING THE ETIOLOGY OF JUVENILE OYSTER DISEASE. Geoffrey C. Horwitz¹, Shawn Polson^{2,4}, Mats Lundqvist,^{2,4} Sara Polson,² Julie Higgins,² Earl J. Lewis,³ Dorothy Howard³ and Cheryl M. Woodley.^{2,4} ¹Trinity University, One Trinity Place, San Antonio, TX 78212; ²NOAA, National Ocean Service, CCEHBR, Hollings Marine Laboratory, 331 Fort Johnson Rd, Charleston, SC 29412; ³NOAA, National Ocean Service, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, MD 21654; ⁴Medical University of South Carolina, Marine Biomedical and Environmental Sciences, Charleston, SC 29412

Juvenile Oyster Disease (JOD) was first observed in 1984 and was responsible for the loss of over 95% of the seed oysters deployed for grow-out in the late 1980's and early 1990's. Hatchery owners have circumvented the disease primarily through improvements in management practices and the development of brood stock less susceptible to JOD. However, because no definitive causative agent has been identified and no simple diagnostic or prevention techniques currently exist, the disease remains responsible for a significant number of oyster deaths and financial losses each year. In this study, mantle tissue from both healthy and diseased (as assessed by the presence of conchiolin) oysters was screened for the presence of the suspected bacterial pathogen, *Roseovarius crassostreae*, and new candidate pathogen-associated protists by examining 16S and 18S ribosomal sequences, respectively. Similar methodologies were also used to examine diagnostic inclusion bodies which had been isolated from histological samples of mantle tissue using laser capture micro dissection. A strong relationship was found between both the presence of *R. crassostreae* and the candidate protist *Paranophrys magna*, but not in the second protist examined, the suctorian *Prodiscophrya* sp. in oysters with diagnostic signs of Juvenile Oyster Disease. While recent literature has ignored the possibility of a protozoan etiology, these results indicate that a protist component of the disease is not only possible, but very likely.

OBSERVATIONS ON AN EPIZOOTIC OF JUVENILE OYSTER DISEASE (JOD) IN KATAMA BAY IN EDGARTOWN, MASSACHUSETTS. Richard C. Karney, Martha's Vineyard Shellfish Group, Inc., Box 1552, Oak Bluffs, MA 02557; John C. Blake, Sweet Neck Farm, Box 1468, Edgartown, MA 02539

In 2003, oyster farmers in Katama Bay on Martha's Vineyard suffered losses of up to 99% of their seed oysters due to an epizootic of Juvenile Oyster Disease (JOD). This was the first confirmed JOD mortality on the farms that have operated in the bay since 1996. The first manifestation of the disease was observed in early August 2003 as a slowed growth rate in 12 mm (average) seed in tidal upweller nurseries. Mortalities and shell deformities were evident by mid September. Juvenile oysters from 2002 cultured nearby in bags on racks also showed slow growth and mortalities in 2003. These oysters were about 50–60 mm when im-

pacted and had mortalities as high as 50%. Some of these 2002 oysters survived the disease but continued to grow slowly to market size and showed a distinctive raised, brown ring on the interior shell surface. JOD related mortalities continued to be observed in oyster seed cultured in the bay in 2004 and 2005 but with reduced intensity. There is evidence for differential survival tied to lineage, and the use of resistant seed stocks is believed to have been key to the improved production in 2004 and 2005.

A SUSPECTED CASE OF JUVENILE OYSTER DISEASE AT GREAT BAY, NEW HAMPSHIRE IN 1984. Richard Langan, Cooperative Institute for New England Mariculture and Fisheries, University of New Hampshire, Durham, NH 03824

A commercial oyster farm in the Great Bay Estuary, New Hampshire experienced heavy mortalities in a cohort of year one Eastern oysters (*C. virginica*) in 1984. One hundred thousand cultchless oyster seed, purchased from a hatchery in Maine, were deployed in stacked trays in May 1984. The trays were suspended from a raft in near-surface waters and maintained at densities equivalent to 80%–100% of the surface area of the trays. The oysters grew from their initial size of 5 mm to approximately 25 mm by September with virtually no mortality. In late September, growers began to notice some gaping oysters with some chalky deposits on the shells. In October, mortalities began to appear and total mortality by the end of November was approximately 30%. Specimens of affected oysters were sent to a shellfish pathologist at the University of Rhode Island. Diagnosis revealed inflammation and degeneration of mantle tissue and conchilin deposits on the shells, however, no pathogenic organisms were isolated. The surviving oysters were transferred from trays to wire mesh cages and placed on bottom over the winter. When retrieved in the spring of 2005, approximately 50% of the oysters were dead. Conchilin deposits were found on the shells of the dead oyster as well as some that had survived. After removing the shells of dead oysters, the survivors were redeployed in bottom cages and grown out to market size over the next two years without any significant mortality. Subsequent year classes of seed that were purchased from the same hatchery were grown in the same location using similar methods without incident.

JUVENILE OYSTER DISEASE (JOD) STUDIES 1991-2005. Earl J. Lewis,¹ C. Austin Farley,² Dorothy Howard,¹ and Tim K. Maugel.³ ¹NOAA, National Ocean Service, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, Maryland 21654; ²NOAA, National Ocean Service, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, Maryland 21654—Retired; ³University of Maryland, Department of Biology, College Park, Maryland 20742

Cultured oysters, *Crassostrea virginica*, moved from Maine to Great Bay, New Hampshire experienced mortalities in 1984.

Shells of dead oysters were unique in the high prevalence of conchiolinous deposits on the interior of the shell. By 1990, cultured oysters throughout the northeast region experienced mortalities in first year oysters 10–30 mm in shell length. The disease, juvenile oyster disease (JOD), only caused mortalities in cultured *C. virginica* juveniles although juvenile hard clams, *Mercenaria mercenaria*, oysters, *Ostrea edulis*, and other invertebrates were cultured in or inhabited nearby waters. All genetic strains of *C. virginica* evaluated were susceptible to JOD and the disease was found to be the same in oysters from Maine South to New York. Multi-year studies showed oysters experience fast growth and feed well until an abrupt cessation of growth and the start of mass mortalities. Affected oysters show no new shell growth and produce conchiolinous deposits on the interior shell that partially or completely encircle the oyster. As the disease progresses, oysters develop mantle recession and the adductor muscle of some oysters migrate over areas of conchiolin and loses its ability to tightly close the shell. In some cases oyster meats detach and float free of the shells. Mortalities of 60–80% are not uncommon and may approach 100% in some groups. Survivors of JOD often have shell checks, thickened ridges or growth rings that correlate with the size of the oyster at disease onset and perhaps recurrence of the disease. Bacteriological studies of mantle tissue, shell lesions, and shell fluid showed comparable bacterial flora and counts in infected and uninfected oysters from numerous locations. Protistan cultures commonly yielded parasitic ciliates, such as *Mesanophrys* sp., *Metanophrys* sp., *Paranophrys* sp., and a suctorian *Endosphaera* sp., that were isolated only from JOD infected oysters and water from JOD affected sites. When examined by histology, affected juvenile oysters have focal mantle lesions containing intracellular inclusion bodies that possess a single nucleus with condensed Feulgen-positive material or one large and a smaller secondary Feulgen-positive body like the macro and micro nucleus of a ciliate. Mantle lesions progress in size and number and ultimately form ulcerations. Mortalities were shown to peak one week after mantle lesions peak and begin to drop one week after lesions begin to resolve. A battery of special stains revealed no further information on identification of the small round bodies or cause of the disease. Electron microscopy showed the intracellular bodies to contain what appear to be nuclei with condensed chromatin, but usually lacking a nuclear membrane.

JUVENILE OYSTER DISEASE (JOD)-TRANSMISSION, THERAPEUTIC TREATMENT, AND DISEASE RESISTANCE STUDIES. Earl J. Lewis,¹ C. Austin Farley,² Dorothy Howard,¹ David Relyea,³ Joseph Zahltla,³ and Gregg Rivara.⁴

¹NOAA, National Ocean Service, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, Maryland 21654; ²NOAA, National Ocean Service, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, Maryland 21654 – Retired; ³Frank M. Flower and Sons, Inc., 34 Ludlam Ave, Bayville, NY 11709; ⁴Cornell Marine Center, 3690 Cedar Beach Road, Southold, NY 11971

Early studies suggested juvenile oyster disease (JOD) was caused by an infectious agent rather than a genetic, nutritional, toxin, or environmental condition. In addition, the movement of oysters from JOD-infected locations often appeared to cause the outbreak and continuance of disease at previously unaffected culture facilities. Field studies at Long Island New York sites routinely showed disease onset was three to four weeks after water temperatures exceeded and remained $\geq 20^{\circ}\text{C}$; mortalities then continued throughout the growing season. Multiple laboratory experiments conducted over several years showed the disease was transmissible to different genetic stocks of oysters, *Crassostrea virginica*, using infected oysters and size specific fractions of material filtered from growing water at infected culture facilities by standard bag filters (5–100 μm). The disease was transmitted at salinities above 18 ppt. the onset of disease was three to seven weeks depending on water temperature, and the 10–25 μm size fraction of filtered material produced the heaviest mortalities and highest prevalence of conchiolin. Transmission rarely occurred from inoculums filtered at 1–5 μm and the infectious agent was not found to pass the 1 μm filter. This may partially explain why on occasion batches of oysters from some hatcheries reared in 5 μm filtered water developed and transmitted JOD when relocated and others from the same batch remained unaffected by the disease. In each case, results of laboratory experiments supported findings of field studies. Oysters produced typical conchiolinous shell lesions and mortalities comparable to those observed in natural infections. Saltwater aquarium medications used to treat infected oysters had differing affects on the disease progression. Maracyn (erythromycin), recommended for treatment of gram-positive bacterial infections, was the most effective medication to reduce mortality in JOD-infected oysters. Two effective ways to manage the effects of JOD is to spawn oysters earlier, allowing them to grow above 30 mm in size before disease onset, and development of disease resistant strains. One year old oysters, selected for survival of JOD and the presence of multiple severe shell checks (thickened ridges or growth rings believed to be evidence of surviving JOD infection), were spawned and reared under normal culture protocols by Frank M Flower and Sons, Inc. and the Cornell Marine Center. Offspring of these oysters survived JOD far better than susceptible oysters reared under the same conditions. Continued selective breeding of three generations of oysters showed no improvement in resistance. Growers using these spawning methods continue to have minimal losses to JOD.

THE INCIDENCE OF JUVENILE OYSTER DISEASE AT FISHERS ISLAND OYSTER FARM, FISHERS ISLAND, NY. Steve Malinowski, Fishers Island Oyster Farm, Box 402, Fishers Island, NY 06390

During 1988–1990, Fishers Island Oyster Farm attempted to integrate the culture of juvenile oysters, *Crassostrea virginica*, into an existing adult oyster growout system in West Harbor, Fishers

Island Sound, NY. This site (depth = 2–3 m at low water) is significantly influenced by Block Island Sound. Maximum surface water temperature is 22°C. The adult growout system consisted of an array of longlines used to suspend lantern nets. Nets were stocked with one year old oyster seed (size range approx. 30–50 mm) obtained from Ocean Pond, Corp., a producer of seed oysters utilizing a salt pond (salinity = 12–20 ppt) on Fishers Island, NY. Growout of this large seed to market size occurs in 6–18 months. In an effort to increase the quantity of large seed oysters available to stock this system, 1mm juveniles were cultured in a land based upwelling system, grown to a size of 4 mm, and stocked in pearl nets (34 × 34 cm) at densities ranging from 200–500 oysters per net. The pearl nets, in vertical arrays of 4 nets, were deployed at the adult growout site during July for 3 consecutive years. Each year, an initial period of satisfactory growth was followed by an episode of high mortality (50–95%) during August. Conchiolin deposition was noted in live and dead oysters all three years. After three years, culture of first year oysters was abandoned at this site. Since then, seed production at the salt pond, where JOD has never been observed, has been increased and provided 100% of the 30–50 mm seed required to stock a significantly expanded adult growout system in West Harbor.

JOD AT OYSTER BAY, NEW YORK. David Relyea, Frank M. Flower & Sons, Inc., P.O. Box 88, Oyster Bay, NY 11771

In July of 1990, Frank M. Flower and Sons (FMF) experienced it's first hatchery oyster seed mortalities from Juvenile Oyster Disease (JOD). At the time it was called "Unexplained Mortality". Samples were sent to NMFS, Rutgers and VIMS. No pathogen was identified. Heavy mortalities continued in '91, '92, and '93. During that time Frank M. Flower was learning how to cope with the problem as research progressed. By 1994, oyster seed production was back to normal levels due to strategies developed by FMF in conjunction with researchers. To date it is still questionable as to what actually causes JOD.

FIELD TRANSMISSION OF JUVENILE OYSTER DISEASE ON LONG ISLAND AND FLOW/DENSITY/MORTALITY STUDIES. Gregg Rivara, Cornell University Cooperative Extension of Suffolk County, Southold, NY 11971; Stan Czyzyk, Long Island Mariculture Technologies, Holbrook, NY 11741

Field transmission of JOD to the Suffolk County Marine Environmental Learning Center (SCMELC) occurred with transfer of broodstock and seed oysters in 1992 and 1993 from Long Island hatcheries. In 1994 a flow/density study was undertaken at the SCMELC with support from NOAA's Oyster Disease Research Program.

A three tank, 27 silo upflow nursery system was constructed. Each tank served as a flow treatment; low (4 L/min per silo), medium (20 L/min) and high (40 L/min). Within each tank three

target stocking densities were triplicated: low (one liter per silo), medium (six liters) and high (12 liters). Tanks were fed unfiltered creek water from a 3.4 m³ head tank filled by two 2-horsepower centrifugal pumps.

Silo units were initially stocked on 11 July 1994. Shell height at this time averaged 8 mm and stocking densities were well below targets. Each week, for a period of nine weeks, the volume and mortality (number dead per 100 randomly-selected oysters) of each silo, along with shell height measurements (live and dead) were recorded. Physical parameters measured weekly included temperature, salinity, Secchi depth and a check of flow rates. As the actual volume exceeded the target volume for each silo, oysters were randomly removed to bring the volume back down to the treatment level.

Substantial mortalities (>20%) were seen by week three in low flow silos; by week four mortalities in these silos averaged 60%. At this time mortalities in high flow silos were at or under 33%, and remained at this level until the end of the experiment. Weekly volumetric increases were higher in medium and high flow silos as compared to low flow silos. Flow affected growth and survival more than stocking density.

It is not known to what degree nutritional stress caused by low flows and high densities affects the manifestation of JOD. It is suggested that silos can be highly stocked without excessive mortalities as long as relatively high flow rates are maintained; at the SCMELC this equates to 0.03 liters of flow per square centimeter of silo screen. These results prompted the development of the axial flow floating upweller system at Cornell in 1995.

Anecdotally, the authors saw free-floating oysters in silos during these experiments and in years prior. Upon observation with a dissecting scope, these oysters were found to be alive. It is hypothesized that the cause of death from JOD is the self "shucking" of the oyster when at least one adductor muscle attachment site is severed by conchiolin deposition, causing the oyster to lose control of its gape and its ability to keep potential pathogens and predators out of the shell cavity.

This project was supported by NOAA award NA47FL0174.

JUVENILE OYSTER DISEASE (JOD) IN CRASSOSTREA VIRGINICA: SYNTHESIS OF KNOWLEDGE AND RECOMMENDATIONS. The Juvenile Oyster Disease Workshop held in conjunction with the 26th Milford Aquaculture Seminar chronicled two decades of an industry's fight against juvenile oyster disease to save their businesses; their partnership with the research community to find the causative agent(s) for this devastating disease of cultured young oysters; and their experiences in learning how to manage this disease to keep an industry alive.

THE ISSUE

Juvenile oyster disease (JOD) is a significant disease of juvenile cultured oysters in the Northeastern United States. The earliest report dates back to the mid-1980's, however the peak of the devastation experienced by most nursery operations occurred in the 1990's. Those able to withstand the economic losses wrought by this disease did so by devising effective management methods and the disease no longer affects the viability of those commercial operations. Nevertheless, as new oyster aquaculture ventures emerge in the Northeast (driven in part by the need of fishing communities to retool after the devastating collapse in numbers of feral finfish and shellfish in the area), JOD outbreaks continue to appear sporadically in other culture sites previously thought to be unaffected or those only rarely affected. The annual variability in occurrence and intensity often results in unexpected and marked economic loss to individual producers. Basic and applied research conducted over the last 20 years has resulted in significant advances in our knowledge of the disease, its etiology, and methods for its mitigation; however, questions remain. A more thorough understanding of the disease pathogenesis, including host/pathogen interactions and other factors (i.e., anthropogenic or physical and/or biological agents in the environment) that contribute to JOD-epizootics, will facilitate the development of reliable surveillance measures for early warnings, help identify threat levels for a given location, and provide a basis for growers and regulators to make informed decisions.

THE DISEASE

JOD is generally observed after water temperatures have reached 20°C and at sites where salinities are above 18 ppt and primarily affects animals between 15–25 mm in shell height. The first clinical sign of the disease syndrome is decreased growth followed by the appearance of gross signs that include extreme cupping of the left valve, loss of the growing edge of the right valve resulting in uneven valve margins with retraction of the mantle edges within the shell (mantle recession) and deposition of abnormal brownish layers of conchiolin (organic shell matrix) on the inner surface of the affected shells. Mortality, which may reach 90%, begins within a week or two of the onset of slowed growth. Conchiolin deposition (a non-specific host response by oysters) is often observed in the form of a raised ridge around the retracted mantle edge. The conchiolin layer may also interfere with attachment of the adductor muscle. Histological lesions in the mantle occur before abnormal conchiolin is deposited. Depending on the

size of the animals, not all of the particular clinical signs may be present in an individual oyster (however they can be observed within a random sampling of a production lot). For example, oysters less than 15 mm shell height often die before they are able to mount the characteristic conchiolin response. Animals between 15 and 25 mm shell height typically show all gross signs of disease (including abnormal conchiolin deposition and uneven valve margins). In addition, the highest mortality rates occur among oysters that are less than 25 mm. Juveniles over 25 mm shell height often show abnormal conchiolin deposition, but growth effects (including uneven valve margins) and accompanying mortality are less common. Animals surviving JOD may develop external shell checks that result when normal growth is resumed.

Typical histological findings with JOD begin early in the disease process. Initially, there is increased hemocytic inflammation in the sinusoidal tissues of the mantle underlying the shell epithelium that is associated with attenuation and cuboidal metaplasia and/or hyperplasia of shell epithelium. In more advanced lesions, necrosis of shell epithelium occurs, resulting in ulceration and severe hemocytic inflammation. Other histological findings include diapediasis of hemocytes across the epithelium into the extra-pallial space (located between the epithelium and shell), accumulation of necrotic cellular debris and bacteria between layers of abnormal conchiolin in that space and occurrence of small coccoid bodies in the affected epithelium. Although the precise cause of death is unknown, these lesions may result in destruction of the adhesion between the shell and adductor muscle causing a critical loss of function. Secondary infections, loss of hemolymph and generalized physiological dysfunction also may contribute to death.

Advances in management practices that are effective in helping to control JOD include:

- Increasing water flow in nurseries, including the use of floating upweller systems and mesh sizes of 6 mm or greater in grow-out containers.
- Decreasing stock density.
- Selective breeding has resulted in some stocks of oysters that demonstrate enhanced tolerance to JOD.

THE AGENT

No set of criteria can provide absolute proof of causation but that guideline can, and should, be used to weigh evidence (Sir Austin Hill, 1965)

In the late 1800's Robert Koch recognized the need for defining a causal relationship between a microbe and a specific disease. His postulates have since been used to guide the collection of evidence to determine if a given organism is the cause of a disease with the proof lying in the concordance of the evidence. Ideally, one should show 1) the parasite occurs in every case of the disease and under circumstances that can account for the pathology and clinical course of the disease; 2) the parasite occurs in no other disease as a fortuitous and nonpathogenic parasite; and 3) after being isolated from the body and repeatedly grown in pure culture, the parasite can again induce the disease and be reisolated. These postulates illustrate the underlying principles:

- Demonstration of a specific association with disease serves to rule out a commensal relationship.
- Isolation in pure culture on laboratory medium proves the existence of an independent living organism and provides a pure inoculum.
- The ability to reproduce disease by exposure to the pure culture of the microorganism demonstrates pathogenicity.
- The ability to re-isolate the microorganism in culture from an experimentally infected host strengthens the case and demonstrates replication within the animal.
- The microbiological evidence should also be in agreement with the pathological and circumstantial data.

Based on these postulates and additional supporting evidence, *Roseovarius crassostreae*, has been established as the etiological agent of JOD. This novel species is a gram-negative bacterium within the *Roseobacter* clade of the marine Alphaproteobacteria, and is the numerically dominant bacterium isolated from JOD-affected oysters. Their relative abundance was confirmed using a culture-independent approach (i.e. sequence analysis of 16S rDNA libraries from affected oysters). The association is consistent regardless of time, location or size of the animals. Thus, *R. crassostreae* is the only organism that completely satisfies Koch's first postulate. In agreement with Koch's second postulate, *R. crassostreae* is not found associated with any other oyster disease and is not found in healthy individuals. (Interestingly, a close relative has been implicated in black-band disease of corals, but the bacterium has not been isolated in culture). Both mortalities and JOD-like conchiolin have been induced in healthy oysters under laboratory conditions when challenged by injection with *R. crassostreae*, and the bacteria were re-isolated from affected individuals. *R. crassostreae* has also been detected in oysters coincident with the earliest microscopic lesions and at least one week prior to the appearance of gross JOD-signs. The bacteria appear to use polar fimbriae to preferentially colonize the inner shell surface, including the conchiolin deposits. Consistent with previous histological studies, *R. crassostreae* do not appear to invade the oyster soft tissues.

The disease can be spread directly among animals, but factors influencing its emergence are not well understood. Minor genetic variations in the 16S–23S rDNA internal transcribed spacer (ITS) region sequences of *R. crassostreae* strains have been identified and used for epizootiological applications. The data indicate that widespread dispersal of genotypes occurs more quickly than the time required for even slight divergence in the ITS. Some data also suggests that most new cases of JOD arise from indigenous *R. crassostreae* and that prolonged use of shellfish culture sites may contribute to their enrichment in those sites. Some *R. crassostreae* introductions may have resulted from direct transfer of adults or seed oysters.

It is still possible that other bacteria and/or protists may play a role in predisposing oysters to JOD or in the disease process itself. For example, JOD frequently occurs soon after exposure of the seed to a phytoplankton or zooplankton bloom, which in turn may be followed by a bloom of *Vibrio* spp. Whereas no particular *Vibrio* species has ever been associated with JOD, increases in total *Vibrio* levels in the environment (and in the oysters themselves) have been associated with at least some JOD outbreaks.

Elevated *Vibrio* levels, which appear before JOD symptoms and persist as the disease develops, may also contribute to mortality. In a recent molecular study into a possible protistan involvement in JOD (using cloned 18S ribosomal RNA sequences), a ciliate, *Mesanophrys magna*, was identified in a population of JOD-affected animals. Subsequent PCR-based screening of those same oysters with primers specific for *M. magna* and *R. crassostreae* showed highly significant correlations with the presence of these two microbes in diseased tissues.

CONCLUSIONS

After reviewing the history and findings presented during this workshop the invited external panel and members of the workshop recognize that significant advances in understanding the etiology of JOD have occurred. Nevertheless, they emphasize that many questions remain unanswered. They were asked to 1) identify salient gaps in our understanding of this disease and its process that will improve the management and control of JOD and 2) make recommendations as to the strategic research needs. The recommendations they put forth are as follows:

- Characterization of the environmental, physical and biological conditions that drive the disease process (e.g., salinity, temperature, and the potential involvement of algal blooms) will provide information for early warning and devising better management strategies.
- Development of additional (e.g., quantitative) diagnostics for early detection and surveillance of potential areas which may be at risk are needed to limit the spread of the disease.
- Elucidation of the pathogenesis of JOD is needed and includes determining the conditions that facilitate colonization of hosts by *R. crassostreae*, the minimum infectious dose, the identification and regulation of virulence factors, and a more thorough examination of the host responses to the infection.
- Identification of factors associated with oyster development and their role in susceptibility to JOD may provide insight into the restricted period during which the animals are susceptible.
- Understanding defense mechanisms (host response) of infected oysters is needed for insight into the biological basis of resistance.
- The ecology of *R. crassostreae* needs to be further investigated (e.g., factors influencing its distribution and abundance, reservoirs, and possible intermediate hosts).
- Further evaluation is needed of *Stappia stellulata* as a potential bacterial probiotic to prevent *R. crassostreae* colonization of oyster seed and subsequent mortalities.
- Future efforts directed at development of additional disease-resistant strains using information from research as well as survivor breeding will provide excellent management methods for this disease.

ACKNOWLEDGEMENTS

We would like to thank all of the Juvenile Oyster Disease Special Session speakers whose input was invaluable to the synthesis process: Rocco Cipriano, USGS, Kearneysville, WV; Richard Clime, Dodge Cove Marine Farm, Newcastle, ME; Christopher Davis, Pemaquid Oyster Company, Waldoboro, ME;

TWO-YEAR PERFORMANCE OF TWO DISEASE-TOLERANT OYSTER STRAINS IN THE PATUXENT RIVER, MARYLAND. George R. Abbe¹, Carol B. McColough², and Christopher F. Dungan². ¹Morgan State University, ²Maryland Department of Natural Resources.

Extreme mortalities among a standard strain of specific-pathogen-free (SPF) *C. virginica* at three sites in the Patuxent River, Maryland during the 2000–02 drought, led to our search for improved performances from available disease resistant native oyster strains. SPF spat of disease-tolerant CROSBreed and DEBY strains, alongside standard-strain oysters, were set and deployed in September 2003, at our same experimental sites. Mean station salinities ranged from 12.1–16.2 ppt during 2000–02, but have been generally lower since then, although salinity increases were observed during much of 2005. Mean incremental two-year growth was better for all strains combined at the mid- (62.8 mm) and down-river (61.5 mm) sites than upriver (49.4 mm), probably because of occasional marginal salinities at the upriver site during year 1. Two-year growth of DEBYs (64.5 mm) was better than CROSBreeds (56.5 mm) or standards (52.5 mm) based on net shell-length increases. After two years, prevalence and body burdens of *Perkinsus marinus* in experimental oysters are increasing, and light mortalities are beginning to occur, all of which are probably related to increasing salinity and increasing infection levels in feral host populations in the deployment areas. Whether disease levels and mortalities of experimental oysters remain at acceptable levels will depend on future salinities; whether DEBYs or CROSBreeds outperform standards will depend on future salinities and also on functional genetic effects. Differences should be apparent by the end of the third year.

OYSTER (*CRASSOSTREA VIRGINICA*) REEF RESTORATION IN THE BELLAMY RIVER, NH: INITIATION OF A MULTI-SPECIES PROJECT. Holly Abeels, Ray Grizzle, Jennifer Greene, and Krystin Ward. Jackson Estuarine Laboratory, University of New Hampshire.

The eastern oyster (*Crassostrea virginica*) plays an important ecological role in the Great Bay estuarine system, where the populations have declined due to disease and other factors. In 2000, the New Hampshire Estuaries Project (NHEP) developed a management plan with a goal of increasing oyster populations by adding twenty acres of 'restored' oyster bottom by the year 2010. The current project was developed in collaboration with NHEP and the City of Dover, NH to contribute to this goal and to begin multi-species habitat restoration in the Bellamy River estuary. The river bed was surveyed in fall 2004 using a towed video and DGPS system and bottom habitats classified to determine the extent of hard bottom available for planting of 'seed' oysters on cultch. Ten million larvae spawned from Great Bay broodstock were set onto shell cultch in two 3,000-gallon fiberglass tanks located at Jackson Estuarine Laboratory in July 2005. Once settlement had occurred,

the spat were transferred to a nursery raft located in an adjacent cove. After 3 months, approximately 400,000 spat (~40 mm shell height) had survived and were transferred to the study site where twelve mini-reefs were created in a 6000-m² area and one reef created in a 200-m² area. This area is located adjacent to an ongoing eelgrass restoration project, which will allow a multi-species community to develop. Future work will include sampling with towed video, counts and measurements of live oysters, and set out of mussel recruitment devices for transfer to multi-species habitat.

THE ECONOMIC IMPLICATIONS ASSOCIATED WITH BIOFOULING IN SHELLFISH AQUACULTURE. Charles M. Adams¹, Sandra E. Shumway², Robert B. Whitlatch², and T. Getchis³. ¹Florida Sea Grant Extension Program, University of Florida, P.O. Box 110240, Gainesville, FL 32611, ²Department of Marine Sciences, University of Connecticut, Groton, CT 06340, ³Connecticut Sea Grant College Program, Groton, CT 06340.

Biofouling is an important issue to consider when designing a marine shellfish culture system. The costs associated with controlling biofouling in marine shellfish culture systems can be significant. This is particularly true for those systems which utilize the water column for the production process, such as rope, cage, and suspended net systems. This study examined several of the economic implications associated with bio-fouling in marine shellfish culture systems in the northeast U.S. region. A survey was sent to commercial marine shellfish aquaculturists within the region. These operations predominantly culture clams, oysters, and mussels. They utilize a wide variety of culture methods. Each survey recipient was asked to consider the economic implications of bio-fouling on their culture system, as well as their product marketing efforts. Survey recipients were asked to describe how biofouling affected their production, including impacts on growth rate, harvest size, yield, etc. Information on current methods of control was also solicited. Survey recipients were also asked to provide an estimate of the annual costs associated with bio-fouling control. Similar questions were posed regarding the impact that bio-fouling has on the marketability of the harvested product. The responses provide insight into the differential effects that biofouling has on commercial shellfish culture operations, when considering species cultured, production method utilized, culture system location, targeted market, and other factors. This information will be useful when considering the efficacy of future innovative methods for controlling biofouling in shellfish culture operations within the northeast and other regions of the U.S.

OYSTER RECRUITMENT AND EARLY GROWTH PATTERNS IN THE BARATARIA ESTUARY. Cassandra D. Addison and Earl J. Melancon, Department of Biological Sciences, Nicholls State University, P.O. Box 1, Thibodaux, LA 70310.

We documented temporal and spatial spawning, recruitment, and early growth of oysters within the historically productive zone of the Barataria Estuary from April 2004 to November 2005. The

study area falls within the outfall of the Davis Pond Mississippi River Diversion, which has flowed minimally with no measurable impact to oysters. Hence, data reflect responses to natural conditions, especially the synergism of salinity and temperature. During the study there were two reduced-salinity events (<5 ppt), accompanied by two tropical storms and three hurricanes. A spawn and recruitment failure occurred throughout the estuary in May/June 2004 due to low salinities (<5 ppt). Oysters reabsorbed gonad tissue and died by mid-summer, except at the most down-estuary site. The May 2005 spawn proceeded normally, but recruitment failed. Recruitment failure may be due to a lack of food availability. Fortunately, successful fall spawn and recruitment events occurred in 2004 and 2005. Preliminary findings suggest a spatial significance in recruitment abundance, with down-estuary areas best. Individual fall 2004 spat were tagged and placed in cages at two sites. In 11 months, from October 2004 to August 2005, the down-estuary site produced oysters with a mean length of 62.7 ± 7.5 mm, while up-estuary oysters grew to 47.5 ± 7.9 mm. Fall-recruited spat can grow to a desired commercial-sized seed in one year, with the more down-estuary site showing faster growth. This information becomes crucial for natural resource managers and oystermen, especially during low-salinity conditions. Adaptive up-estuary to down-estuary management strategies for seed can be developed to allow diversions and oysters to co-exist.

GROWTH AND GONAD PRODUCTION OF THE SEA URCHINS *HEMICENTROTUS PULCHERRIMUS* AND *ANTHOCIDARIS CRASSISPINA* AMONG ALGAL SERE. Yukio Agatsuma¹, Hisayuki Arakawa² and Kazuya Taniguchi¹, ¹Graduate School of Agricultural Science, Tohoku University, ²Tokyo University of Marine Science and Technology.

To clarify the differences in the growth and gonad size of the sea urchins *Hemicentrotus pulcherrimus* and *Anthocidaris crassispina* among algal sere, the study was conducted in July 2002 at a fucoid bed and a kelp bed in Gobo and two algal turfs in Mihama, Wakayama Prefecture in southwestern Japan. The growth of *H. pulcherrimus* in the fucoid bed and the kelp bed, where the large perennial *Myagropsis myagroides* and *Ecklonia cava* at the climax stage dominated, respectively, are higher than that in the algal turfs dominated by the small perennial articulated corallines at the seral stage. While the most rapid growth of *A. crassispina* was observed in the fucoid bed, the gonad indices (gonad wet weight x100/body wet weight) of both species of the sea urchins were highest in the fucoid bed. These results suggest that growth and gonad production of *H. pulcherrimus* and *A. crassispina* are affected by algal sere as reported in *H. pulcherrimus* and *Strangylocentrotus nudus* in northern Japan, although they differed among dominant species of algae at the climax stage.

ASSESSMENT OF THE ABILITY OF *CRASSOSTREA ARIAKENSIS* HEMOCYTES TO KILL *PERKINSUS MARINUS* IN VITRO. Mohammad R. Alavi, Jose A. F. Robledo, Eric J. Schott, Keiko Saito, Satoshi Tasumi, and Gerardo R. Vasta, Center of Marine Biotechnology, UMBI, University of Maryland, 701 E. Pratt St. Suite 236, Baltimore, MD.

The eastern oyster, *Crassostrea virginica*, has been reduced to such low numbers in the Chesapeake Bay that the introduction of the Asian oyster *C. ariakensis* is being considered by the industry, and state and federal agencies. To assess the susceptibility of *C. ariakensis* to *Perkinsus marinus* (Dermo) we examined the capacity of *C. ariakensis* hemocytes or plasma to kill or inhibit proliferation of *P. marinus* trophozoites, and compared it to that of *C. virginica*. *P. marinus* trophozoites were exposed *in vitro* to oyster hemocytes or plasma (at six infection ratios) for 24 and 72 hrs and the parasite's ability to proliferate after the exposure was assessed by culture in nutrient medium for four weeks, with weekly measurements of cell densities. Although both *C. virginica* and *C. ariakensis* hemocytes apparently reduced the viability of most of the exposed parasites, even at the ratio of 16:1 (hemocytes: parasites) a small proportion of the parasite survived and proliferated upon addition of culture medium. To rigorously discriminate adherent trophozoites from those phagocytosed by the oyster hemocytes, we developed a method based on a chloromethylbenz-amido derivative of a dialkylcarbocyanine dye (CM-DiI), a lipophilic molecule that can remain highly fluorescent when incorporated into cell wall and can be quenched by trypan blue if the parasite remain extracellular. Using this method, both degraded and intact parasite could be detected within hemocytes 24 hrs post-exposure, confirming our previous results. (Supported by grants from the Maryland DNR and NOAA).

EFFECTS OF HARMFUL ALGAE ON OYSTER GROWTH. J. Alexander¹, D. Meritt¹, A. Pareletti¹, S. Alexander¹, D. Stoecker¹ and P. Glibert. ¹University of Maryland Center for Environmental Science.

Introduction of the Asian oyster, *Crassostrea ariakensis*, to Chesapeake Bay is of considerable interest in the broader plans for Bay restoration. Overfishing, loss of habitat, and disease have caused dramatic losses in the native oyster, *Crassostrea virginica*, and it is thought that the Asian oyster may succeed where the native oyster has not because of its high growth rates, among other factors. One of the manifestations of poor water quality in Chesapeake Bay is the development of harmful algal blooms. Critical to an understanding of the potential success of the Asian oyster in Chesapeake Bay is knowledge of the impact of common harmful algae on oyster growth. The first phase of this investigation included a comparison of the effect of harmful algae on spat growth, measured as shell growth, of both *C. virginica* and *C. ariakensis*. Effects of exposure to *Prorocentrum minimum* were compared to that of *Isochrysis galbana*, one of the standard hatchery feed or-

ganisms, and a non-fed control treatment. Valve height of cultch-less test oysters, prepared by grinding away a portion of the shell periphery, following guidelines from the EPA Oyster Acute Toxicity Test, was measured before and after 96 hrs exposure to each treatment. Feces, pseudofeces, and gut contents were also collected from sample animals to compare digestion. Initial results indicate that *C. virginica* was impacted negatively by *P. minimum* to a greater extent than was *C. ariakensis*.

IN VITRO INVESTIGATIONS OF QUAHOG PARASITE UNKNOWN (QPX). Bassem Allam, Deenie M. Buggé and Mickael Perrigault. Marine Sciences Research Center, Stony Brook University, Stony Brook NY 11794–5000.

Quahog parasite unknown (QPX) has been successfully isolated from clams from different geographic locations in the Northeast. This study uses an *in vitro* approach to investigate the virulence and specificity of different QPX isolates. A fluorometric growth measurement technique and a neutral red cytotoxicity assay were used to investigate interactions between QPX and components from different bivalve species and strains. Our experiments demonstrate that QPX produces extracellular virulence factors that are cytotoxic to *M. mercenaria* hemocytes. This cytotoxicity may play an important role in supporting QPX infection and proliferation within the host. Experiments also indicate that QPX growth in *M. mercenaria* is tissue-specific and that some tissues possess anti-QPX properties. For example, host foot tissue supports *in vitro* QPX growth while growth in mantle or gill tissue is strongly inhibited. Bivalve plasma also contains anti-QPX factors which may play a role in host defense. Plasma from species not known to develop QPX disease contains higher anti-QPX activity than *M. mercenaria* plasma. The *in vitro* inhibitory effect of plasma seems however to be time-dependent and lasts up to two days since further incubation results in an enhancement of QPX growth. These and future *in vitro* investigations will increase our understanding of QPX infection and disease development. For instance, studies targeting tissues where anti-QPX activities are localized may provide a good strategy for the determination of biological bases of QPX resistance in clams.

RISKY BUSINESS: PROSPECTIVE LOOK AT TRIPLOID *C. ARIAKENSIS* AQUACULTURE. Standish K. Allen Jr., Virginia Institute of Marine Science, P.O. Box 1346, Great Rd., Gloucester Point, VA 23062.

Among the options under consideration by the current Environmental Impact Statement (EIS) process on the introduction of *C. ariakensis* to Chesapeake Bay is that of aquaculture of triploid *C. ariakensis*. The premise for this option is that sterile triploids can eliminate or lessen the risk of inadvertent introduction. Triploidy is produced by crossing tetraploid with diploid brood stock, yielding high proportions of triploids—but not 100%. Our experience

with certifying eight batches (average sample size for each certification: 3558) of triploids produced in this way indicates that, on average, batches are $99.86 \pm 0.094\%$ (95% CI) triploid. Essentially, the risks posed by triploid aquaculture boils down to the risk of reproduction from the one in 1000 diploids scattered among the crop. We have overseen two major industry aquaculture trials with triploid *C. ariakensis*. Because of Federal permitting requirements by the Army Corps of Engineers for these trials, various other Federal agencies, as well as States and NGOs, have weighed in on provisions for permitting. Risk has been quantified by a simple probability/ demographic model to estimate the number of surviving spat that result from various deployment options. Moreover, these risk calculations have been deemed cumulative, such that those risks posed in a previous industry trial with triploids are summed with those for subsequent ones. Clearly, this approach leads to spiraling impossibility to continue these trials, and seemingly, excludes the opportunity for commercial scale aquaculture. A more “liberal” approach to engaging triploid aquaculture and dealing with its concomitant risks will be discussed.

SHORT-TERM EVALUATION OF MORTALITY FROM BONAMIA SP. INFECTIONS IN *CRASSOSTREA ARIAKENSIS* AT TWO LOCATIONS IN SOUTHEASTERN NORTH. Troy Alphin¹, Ami Wilbur¹, Ryan B. Carnegie² and Martin H. Posey³. ¹UNC-Center for Marine Science, 5600 Marvin K. Moss Ln, Wilmington, NC 28909, ²Virginia Institute of Marine Science, Gloucester Point, VA, ³Department of Biology and Marine Biology, UNC-Wilmington.

The Suminoe oyster, *Crassostrea ariakensis*, has been proposed as a potential aquaculture species for several states along the Atlantic coast of the United States, including Maryland, Virginia, and North Carolina. A 2003 trial of *C. ariakensis* in Bogue Sound, North Carolina, resulted in high mortality due to infection by *Bonamia* sp. The presence of *Bonamia* sp. may represent a significant impediment to the future culture of *C. ariakensis* along the east coast. As part of a field study evaluating the presence of *Bonamia* sp. in coastal North Carolina, *Ostreola equestris*, a species that may serve as a reservoir host, was sampled from a variety of locations from Bogue Sound to Wilmington. *Bonamia* sp. was detected in the Wilmington area in July 2005 and juvenile triploid *C. ariakensis* were deployed at two Wilmington locations in late September to determine if parasite transmission to this non-native species would occur. The first site was a research bottom lease, at the mouth of Hewletts Creek, NC and the location where *Bonamia* sp. was observed in *O. equestris*, while the second site was located 3 km south along the ICW at a site where *O. equestris* had not been noted. *C. ariakensis* were deployed for eight weeks with weekly monitoring of *Bonamia* sp. prevalence and mortality, and biweekly monitoring of growth. *Bonamia* sp. infections in *C. ariakensis* were noted at both locations, with a higher *Bonamia* sp. prevalence

at the research lease site. Peak mortality approached 40% during the 5th week of the study.

IN VITRO PROTEASE PRODUCTION BY QPX. Robert S. Anderson, Tracey M. Luskey and Maureen A. Strauss. University of Maryland Center for Environmental Science, Chesapeake Biological Laboratory, P.O. Box 38, Solomons, MD 20688.

QPX secretes virulence factors, including proteases that contribute to success in its host. *In vitro* production of QPX proteases was followed by zymography for four to six weeks, using trisglycine gels with 0.1% gelatin incorporated as a substrate. Little or no protease activity was detected in unsupplemented Kleinschuster's medium, in which QPX was cultured at 11°, 20° or 27° C. However at 20° C, supplementation with fetal bovine serum (FBS) resulted in the production of 6–7 QPX-dependent proteases, plus 4–5 FBS-associated proteases. After six weeks of incubation, QPX proteases included a >200 kD band plus bands at ~70, 51 and 46 kD; other proteases were weakly or occasionally expressed. The 46 kD band was consistently the major QPX protease. Expression of QPX 46 kD protease showed temperature dependency: it was maximally (+++) expressed by one week at 27° C, but seen as a faint (+/-) band after three weeks at 11° and 20° C. Experiments were carried out to determine if the presence of host tissue extracts in the medium would modify the expression profile of QPX proteases. FBS and homogenate proteases interacted to produce strong bands of activity that made observation of QPX proteases impossible. Therefore, homogenate effects were measured in FBS-free medium. Unique, active (++) ~60 & 65 kD proteases were seen throughout the six week course of the homogenate-QPX study. The major (46 kD) protease in FBS-supplemented cultures was weakly expressed, and only after three weeks. These results suggest that the microenvironment of QPX may influence its pathogenicity.

RETURNING TO SALTWATER POND CULTURE OF CRASSOSTREA VIRGINICA. William D. Anderson¹, William A. Cox² and Jack M. Whetstone³. ¹South Carolina Department of Natural Resources, P.O. Box 12559, Charleston, SC 29422, ²Island Fresh Seafood, Inc., ³Clemson University.

Using saltwater ponds to cultivate oysters can be traced back to the Romans in the first century B.C., and even earlier to Chinese aquaculture. In South Carolina and other east coast states, growing large, single eastern oysters in saltwater ponds and abandoned impoundments has been practiced since the 1800s. South Carolina's renowned "mill pond oyster" floated as spat on logs into saw-mill ponds, grew near the surface, dislodged, and if it survived in the mud bottom environment, matured into an epicurean delight. Oyster culturists observed pond oysters' adductor muscles to be at least one-third larger than their estuarine siblings, ostensibly to avoid smothering by siltation on the mud bottom.

Saltwater ponds generate a favorable environment for controlled autotrophic production and can sustain a higher instantaneous biomass throughout the year compared to adjacent, productive estuarine waters. Through intake filtration, circulation adjustments, salinity and water level control, ponds can be intensely managed to inhibit parasites, predators and disease while accelerating growth.

Optimum conditions for pond and estuarine aquaculture of eastern oysters have evolved recently in SC due to a successful clam mariculture infrastructure seeking diversification, strong market demand for single local oysters, hatchery technology advances and the capacity to cultivate large (>57 mm) juvenile oysters in a controlled environment.

Island Fresh Seafood, a South Carolina Corporation has spawned *C. virginica* seed that has grown 63 mm in six months, considerably faster than wildstock oysters. This presentation discusses salt water pond characteristics, production of seed oysters and South Carolina's cooperative fisheries research initiatives to engender single oyster aquaculture by commercial shellfishermen.

AN OVERVIEW OF BIVALVE POPULATION RESTORATION EFFORTS IN FLORIDA WATERS. William S. Arnold. Florida FWCC Fish and Wildlife Research Institute, 100 8th Ave. S.E., St. Petersburg, FL 33701.

The coastal zone in Florida is being developed at a rapid pace, placing increasing pressure on nearshore marine resources including bivalve molluscs such as scallops, clams, and oysters. In an effort to mitigate the impacts of coastal development and to maintain viable and broadly distributed populations of these species, a variety of approaches have been applied to rebuild or reestablish populations. These approaches include transplanting adults, planting seed, releasing larval or post-larval animals, and constructing habitat. Success has varied considerably depending upon the method employed, the target species, and the interactive effects of species and habitat. Among many lessons that have been learned, one of the most essential is that the cause of collapse must be identified and either ameliorated or circumvented prior to initiating a restoration effort. Otherwise, the likelihood of success is low. Because similar development pressures are either underway or imminent throughout the United States, the lessons learned in Florida should be of interest to a broad array of coastal zone scientists and managers.

DOES DISTANCE FROM SUBTIDAL CHANNEL INFLUENCE USAGE OF NEWLY ESTABLISHED INTERTIDAL OYSTER REEFS BY TRANSIENT AND RESIDENT FAUNA. Stephen J Artabane, Martin H. Posey and Troy D. Alphin. University of North Carolina, Department of Biology and Marine Biology, 601 S. College Rd., Wilmington, NC 28903.

The habitat value of oyster reefs (*Crassostrea virginica*) to many finfish and decapods may vary significantly with landscape factors such as proximity of adjacent habitats, distance to source

areas, and reef architecture. We examined how distance of intertidal reefs from subtidal channels and low tide refuges for transient fauna influences reef use by both resident and transient fauna. Four transects of artificial reefs were created using clean oyster shell and placed at distances of 5 m, 30 m, and 55 m from a subtidal channel on a tidal flat in southeastern North Carolina. Transient finfish and crustaceans were sampled during flood tide using Breder traps and surround nets. Resident species were sampled using shell excavations and sediment cores. Preliminary data suggest preferential use of reefs over non-reef controls and use of edge habitat over interior habitat for the dominant transient species: pinfish, spot and mummichog. Conflicting patterns were observed between both sampling methods for pinfish, with Breder trap data indicating preference for reefs furthest from channel and surround net data indicating preference for reefs closest to the channel. No clear pattern of use was observed for mummichog and juvenile spot. Excavations show higher settlement of oyster spat on reefs located at 5 m from the subtidal channel, but no differences among distances for recruitment of mud crabs, *Panopeus herbstii*. Measurements of predation using tethered grass shrimp, *Palaemonetes pugio*, and outplanted hard clams, *Mercenaria mercenaria*, were conducted to measure actual reef utilization but results were inconclusive.

ENSO AND CRUSTACEAN POPULATIONS OF PERÚ: ARE THE LANDINGS RECORDS RELATED TO THE SEA SURFACE TEMPERATURE? Cynthia M. Asorey¹, Javier Calcagno¹ and Gustavo A. Lovrich², Facultad de Ciencias Exactas y naturales-UBA/CENSOR EU, ²Centro Austral de investigaciones CADIC, Ushuaia/CENSOR EU.

The marine ecosystem of the south eastern Pacific is made up of a particular system of superficial currents that make the coasts of Chile and Peru some of the world's most productive fishing zones. Few studies have been conducted to examine the population dynamics of commercial crustaceans and ENSO. This concern is probably due to the low economic value of these species, when compared to other commercial ones. In this work, mean and maximum temperatures registered at the Chicama station (07° 41' S, 79° 26' W), between 1970 and 1999 were correlated with the crustacean landing records of the Instituto del Mar del Peru. We found a positive correlation between the total crustacean landings of shrimp species (*Litopenaeus spp.*, *Farfantepenaeus californiensis* and *Xyphopeneaeus riveti*) and both the annual mean temperatures ($r = 0.43$, $p < 0.05$) and the maximum temperatures ($r = 0.39$, $P < 0.05$). We also found a negative but not significant, correlation ($r = -0.22$ for the mean SST and $r = -0.28$ for the maximum SST, $p > 0.05$), for the crab species (*Cancer sp.*, *Platyxanthus sp.*). These results coincide with earlier works that report on the increase of mortality rates and migrations to deeper water of crab species. Coincidentally, during the ENSO, commercial shrimps

move south from off Ecuador to off Perú, where fishers adapt their fishing arts to catch shrimp.

INFLUENCE OF TEMPERATURE ON THE METABOLISM OF *MUNIDA GREGARIA* (= *M. SUBRUGOSA*) (CRUSTACEA: ANOMURA). M. C. Avalos¹, O. Heilmayer² and K. Paschke³, ¹CADIC (Centro Austral de Investigaciones Científicas), Ushuaia, ²Alfred Wegener Institute for Polar and Marine Research, Brem., ³Instituto de Acuicultura—Universidad Austral de Chile, Pue.

Munida gregaria is an epibenthic galatheid crab of 5 to 7 cm total length that has a key role in the coastal subantarctic ecosystem of South America. Although plenty of information on the species related to growth, reproduction, abundance and distribution is available not much is known about physiological adaptations to subantarctic temperatures. This preliminary study aimed to determine standard and active metabolism of *M. gregaria* acclimated at three different temperatures. Animals were caught off Puerto Montt (47°S), Chile, with an underwater vacuum at ~10 m depth. Oxygen consumption of animals ($n = 6$ per treatment; mean carapace length = $13.5 \text{ mm} \pm 1 \text{ mm}$) acclimated to 6°, 12° and 18°C was measured. A closed system was used for respiration measurement. Oxygen content was determined with microoptodes connected to a single channel MICROX TX3 array. After standard metabolism (defined as oxygen consumption of unfed, unstressed animals) was measured, animals were forced to move and be active. Oxygen consumption was measured to obtain active metabolism. Results show that standard metabolism of *M. gregaria* was significantly positive affected by temperature ($6^\circ\text{C} = 0.105 \text{ mgO}_2 \cdot \text{h}^{-1} \cdot \text{g}^{-1}$; $12^\circ\text{C} = 0.161 \text{ mgO}_2 \cdot \text{h}^{-1} \cdot \text{g}^{-1}$; $18^\circ\text{C} = 0.232 \text{ mgO}_2 \cdot \text{h}^{-1} \cdot \text{g}^{-1}$). Active metabolism, however, could only be measured in few animals. In the cases the animals showed high levels of activity, a significant non-temperature dependent 2 to 3 fold increases in their oxygen consumption was measured. Our data provide preliminary insight into the physiology of this key species and help setting future experiments on this species, in order to study its thermo-tolerance in a latitudinal temperature context.

INFLUENCE OF SALINITY ON THE DISTRIBUTION AND ABUNDANCE OF LARVAE OF DOMINANT OYSTER-REEF DECAPODS IN SOUTHWEST FLORIDA. Bethany M. Bachelor¹, S. Gregory Tolley¹ and Scott E. Burghart², ¹Florida Gulf Coast University, Coastal Watershed Institute, 10501 FGCU Blvd S., Ft. Myers, FL 3396, ²University of South Florida, College of Marine Science.

Spatial and temporal variability in recruitment of associated organisms to oyster reefs is dependent upon a number of factors including larval supply, which, in turn, is influenced by freshwater

inflow and salinity. Distribution and abundance of larvae of the three dominant decapod crustaceans found on oyster reefs in Es-tero Bay, Florida (*Petrolisthes armatus*, *Eurypanopeus depressus* and *Rhithropanopeus harrisii*) were quantified using monthly plankton tows. Sampling included stations near passes connecting to the Gulf of Mexico, in the open waters of the bay, and in association with tidal tributaries. Larval densities of the marine stenohaline *P. armatus* were greater in bay waters and near passes. Larvae of the euryhaline *E. depressus* occurred abundantly throughout the bay and in association with tidal tributaries. Larvae of *R. harrisii*, a species known to favor reduced salinities, were most abundant near tidal tributaries. Densities of *P. armatus* and *E. depressus* peaked at the end of the dry season (May) and were depressed with the onset of seasonal rains (June). In contrast, *R. harrisii* larvae were in short supply during dry months but were abundant during the wet season. Weighted mean salinity of capture was higher for *P. armatus* (29.72) and *E. depressus* (29.88) than for *R. harrisii* (6.72), and larval density was positively correlated with salinity of capture for *P. armatus* and *E. depressus* and negatively correlated for *R. harrisii*. These results suggest the importance of considering the effects of salinity on spatial and seasonal variation in larval supply in understanding recruitment dynamics of oyster-reef associates.

LIFE HISTORY CHARACTERISTICS OF THE NONNATIVE GREEN MUSSEL (*PERNA VIRIDIS*), IN TAMPA BAY, FLORIDA. Shirley Baker¹, Bruce Barber², Jon Fajans³ and Patrick Baker¹. ¹University of Florida, Department of Fisheries and Aquatic Sciences, 7922 N.W. 71st St., Gainesville, FL 32611, ²Eckerd College, ³Keys Marine Laboratory.

The green mussel, *Perna viridis*, has been intensively harvested and cultured for human consumption throughout its native range and has been transplanted outside its range numerous times for aquaculture. In August 1999, *P. viridis* was identified in Tampa Bay, Florida, the first report from North America. The overall objectives of our three-year research program were to monitor and predict the spread of *P. viridis* and major interactions with native bivalve species and phytoplankton communities. Here we examine the reproduction, recruitment, growth, and survival of *P. viridis*. Monthly samples were examined histologically for reproductive status and settlement plates were used to examine recruitment. Monthly quantitative samples were collected to estimate size distribution, cohort growth and survival. Based on both histological and recruitment data, *P. viridis* in Florida, as in Asia, has a primary spawning peak in spring and a lesser peak in autumn. Patterns were strongest in peak habitat (based on *P. viridis* density); the autumn peak timing or intensity varied in areas of lower *P. viridis* density. Growth rate was rapid—about 9 mm per month—and within the

range of growth rates reported in native habitats. Based on size, some *P. viridis* may become sexually mature and attain fishery size (~70–80 mm) within one year. As demonstrated in this study, green mussels successfully reproduce in Florida, resulting in dense populations throughout Tampa Bay.

RESTORATION OF INTERTIDAL OYSTER REEFS AFFECTED BY INTENSE BOATING ACTIVITY IN SHALLOW FLORIDA WATERWAYS. Andrea Barber¹, Linda Walters¹ and Anne Birch². ¹University of Central Florida, ²The Nature Conservancy.

In recent years, intertidal reefs of the oyster *Crassostrea virginica* in central Florida's coastal areas have suffered extensive losses due to wakes from recreational boats. The creation and enforcement of "no wake" zones in the area are unlikely. Thus there is an urgent need for an alternative restoration strategy before oyster reefs decline past the point of no return. The goal of this project is to implement a scientifically-based restoration technique that minimizes wake damage from recreational vessels on intertidal reefs in Canaveral National Seashore (CANA). To accomplish this, we will test a range of restoration measures to determine the optimal design that best increases: 1) the numbers of oysters, 2) 3-D structure of our intertidal reefs, and 3) biodiversity and abundances of sessile and motile species on reefs. These restoration measures will include all combinations of leveling piles of disarticulated shells on reefs, placing seagrass seaward of reefs, and deploying miniature, mobile oyster reefs (restoration mats) to provide substrate for oyster recruitment and survival. Our restoration mat design includes affixing 36 drilled oyster shells to 0.4 × 0.4 m² pieces of black mesh. After completing this experimental objective, the majority of our effort will be to implement our optimal design to increase reef dimensions to historical levels within the bounds of CANA. Our goal is to restore 15–20% of the 400 reefs (60–80 reefs) in the project area (approximately 40 acres) that have been damaged by wakes from recreational vessels.

THE NEW ZEALAND SEA URCHIN (*EVECHINUS CHLOROTICUS*) FISHERY. M. F. Barker, Department of Marine Science, University of Otago, Box 56, Dunedin, New Zealand.

Evechinus chloroticus (Valenciennes) known locally as "kina" is a ubiquitous echinometrid sea urchin, endemic to New Zealand. It is one of the largest sea urchins known, with a maximum test diameter (TD) of 16–17 cm and is widely distributed around the main islands of New Zealand but is also found at the Chatham Islands to the west, and the Snares Islands to the south. It is generally found on rocky reefs in water less than 12 to 14 meters

deep although intertidal populations also occur, mainly in the north of the North Island. Adult urchins are normally found in areas with moderate currents and wave action, and are seldom found in areas of extreme exposure such as the surf shores that occur along much of New Zealand's west coast.

It was harvested by Maori people before the arrival of Europeans in New Zealand and was first harvested commercially in about 1983. In 2002 it was included in the New Zealand Quota Management System, of 10 regions around the country used to manage all of New Zealand's larger commercial fisheries. At the present time fisheries are supplying the domestic market almost exclusively because the poor taste and colour of the roe has resulted in low prices from export to S.E. Asia.

In this talk the long term viability of the fishery will be discussed. Strategies to mitigate the effects of overfishing including better management of the quota system, roe enhancement and reseedling will also be discussed.

ENHANCEMENT OF YIELD AND QUALITY OF *EVECHINUS CHLOROTICUS* ROE THROUGH CONTROLLED DIET. M. F. Barker¹, P. Bremer², P. Silcock², C. Delahunty², and M. Sewell³. ¹Department of Marine Science, ²Department of Food Science University of Otago, Box 56, Dunedin, New Zealand, ³School of Biological Sciences, University of Auckland, Auckland, New Zealand.

Export of New Zealand sea urchins; roe to Japan and other south-east Asian countries has been unsuccessful as the fishery does not consistently produce roe with marketable qualities. Previous research in our laboratory has shown that by holding animals in the laboratory or in sea cages, and feeding a gelatin bound or Wenger diet for ~8 to 12 weeks the yield of Kina roe can be significantly enhanced although the colour of such roe was often highly variable. The influence of diet on the colour or flavour of the roe was not quantitatively assessed. The present research was initiated to: 1) develop local diet formulation in commercial quantities, and 2) gain a better understanding of the relationship between the sensory and biochemical characteristics of urchin roe and the animals' diet.

Gonad data quantified to date include: gonad index 23–24%; colour (58.6–66.9° hue angle, 17.3–34.8 chroma); glucose concentration (0.1–0.8% dry weight basis (dwb)); glycogen concentration (8.5–16.6% dwb); and free amino nitrogen concentration (1.4–2.5% dwb). Gonad indices are significantly higher in urchins fed artificial compared to algal diets but not higher than animals collected from the wild. Free amino acids are believed to contribute significantly to the taste of sea urchin roe. We have determined that glycine is present in the highest concentration followed by

alanine and valine, though the relative amount of individual free amino acids varied between roes from different animals. We are also carrying out tests to determine the impact of handling and storage regimes on the shelf-life of *E. chloroticus* roe.

PARTICULATE MATTER PRODUCTION ASSOCIATED WITH DEEP-WATER SUSPENDED PACIFIC OYSTER (*CRASSOSTREA GIGAS*) FARMS IN BRITISH COLUMBIA.

P. A. Barnes, W. Friesen and S. Switzer, Centre for Shellfish Research, Malaspina University-College, 900 5th St., Nanaimo, B.C. V9R5S5, Canada.

The economic importance of bivalve culture in coastal areas of the northeastern Pacific is not reflected in the amount of information available on the environmental interactions of culture facilities. This study was designed to determine the fate of the particulate material produced by deep-water, suspended Pacific oyster farms in British Columbia. Data was collected quarterly for one year at two sites of contrasting current regimes. Seven stations, including two reference stations, were sampled at each site along a transect running through the centre of the oyster farm. Sediment trap data yielded deposition rates, including rates for TOC/TIC and TN. Chemical and biological parameters were measured on sediments at all sites. Water column data collected include plankton community composition, particle size and abundance, and a suite of environmental variables including salinity, temperature, dissolved oxygen, pH, turbidity/total suspended solids and chlorophyll. The results of preliminary analyses investigating relationships between depositional data, water column variables and benthic data for the seven stations at each of the two sites are discussed, in addition to seasonal trends.

INVERTEBRATE BIODIVERSITY ASSOCIATED WITH DEEP-WATER PACIFIC OYSTER (*CRASSOSTREA GIGAS*) FARMS IN BRITISH COLUMBIA, CANADA.

P. A. Barnes¹, S. Switzer¹ and B. Burd². ¹Centre for Shellfish Research, Malaspina University-College, 900 5th St., Nanaimo, B.C. V9R5S5, Canada, ²Eco-Stat Research Ltd.

Diverse invertebrate communities ("fouling" communities) are associated with B.C.'s deep-water, suspended shellfish culture systems. The three-dimensional structure of these systems increases habitat complexity and provides hard substrate for larval settlement. These diverse communities require investigation to determine their role in the environmental interactions of shellfish aquaculture, to document invasive species and to assist in documenting B.C.'s coastal marine biodiversity. This study monitored fouling

communities associated with deep-water suspended oyster rafts at two sites of contrasting current regimes. Biodiversity data were collected in the summer, winter and spring; organisms were identified to species, or the lowest taxon possible using the current taxonomic literature. Community composition data are presented, along with results of preliminary data analysis investigating changes in community composition with depth, site and season.

HOW EFFICIENT IS THE BLUE MUSSEL (*MYTILUS EDULIS* L.) AT FILTERING EXCESS PARTICULATE MATERIAL AT AN INTEGRATED AQUACULTURE SITE?

Aaron T. Bennett¹, Bruce A. Macdonald¹ and Fred H. Page².

¹University of New Brunswick (Saint John), P.O. Box 5050, Saint John, NB, E2L 4L5, Canada, ²Fisheries and Oceans Canada; University of New Brunswick.

In 2001, a collaborative project investigated the viability of integrated aquaculture (finfish/shellfish/seaweed) in the Bay of Fundy. The project will help to quantify the economic and environmental benefits and to serve as a model for developing integrated, sustainable aquaculture. The present study has two main objectives: 1) characterizing the suspended particle field within and surrounding an integrated aquaculture site using various methods to capture the entire size range of suspended particulates and 2) determining the uptake and absorption of suspended particles on the integrated aquaculture site by the blue mussel, *Mytilus edulis*. We are using videography to capture the size distribution of undisturbed particles from a minimum of 100 µm to the upper range of particle size limit. Particles smaller than the range of the video resolution are measured using a Coulter Multisizer which results in a size distribution pattern for individual particles measured. In order to obtain a more complete picture, a biodeposition rate is calculated from the feces and pseudofeces deposited by the mussels during the feeding trials. A net rate is then calculated for the amount of particulates completely removed from the system. We believe this research will support the assumption that mussels play a vital role in the environmental sustainability of integrated aquaculture in the Bay of Fundy.

OPTIMIZATION OF GROW-OUT CONDITIONS FOR THE LARGE SCALE CULTURE OF QUEEN CONCH, *STROMBUS GIGAS*. Anne Boettcher¹, Julie Davis² and Catherine Dyer².

¹University of South Alabama, Biology Department, USCB 124, Mobile, AL 36688, ²Caicos Conch Farm, Trade Wind Industries.

Queen conch has long been a staple within the Caribbean, and wild product is exported to an ever increasing global market. However, rising fishing pressure has resulted in the depletion of wild stocks which has increased interest in both research and commercial based aquaculture programs. The Caicos Conch Farm, a facility involved in the commercial-scale culture of queen conch, has

well established hatchery and juvenile rearing techniques and is in the process of optimizing onshore and offshore systems for the grow-out of conch. Recent studies focused on evaluation of pelleted test diets and determinations of feed conversion ratios. Increases in conch growth are seen with the inclusion of natural algal components to feed, and pellet formulations that include an alga base or algal mimetics are being developed. Feed conversion ratios similar to those seen for other aquaculture species are achieved with the current pelleted diet. In conjunction with an evaluation of onshore pond systems and offshore pen design, stocking densities and transfer protocols for conch in these systems are being evaluated. The technology developed through these studies will be implemented in a new grow-out facility on Grand Turk.

APPLICATION OF PHOTOPERIOD MANIPULATION AND NEW EXTRUDED DIETS IN SEA URCHIN AQUACULTURE. S. Anne Boettger¹, Charles W. Walker¹, Michael G. Devin², Stephen A. Watts³, Mickie L. Powell³ and Addison L. Lawrence⁴.

¹The University of New Hampshire, Department of Zoology, 46 College Rd., Durham, NH 03824, ²Peacock Canning Company, ³The University of Alabama at Birmingham, ⁴Shrimp Mariculture Research, Texas A&M System.

For the past two decades, sea urchin fisheries have become important commercial resources with US exports to Japan exceeding \$150 million in 1995. However, sea urchin populations along the coasts of the US have been overexploited. In the largest US urchin fishery (State of Maine), landings and numbers of licensed urchin fishermen have declined between 1993 and 2001. To develop new aquaculture techniques and more effective diets we have used information on cellular changes occurring during gametogenesis. Individuals were exposed to ambient and July photoperiod, fed an extruded diet (Wenger) and were evaluated for gonad index, stereology of different gonadal cells, nutritive phagocyte and oocyte sizes and taste. Gonad indices (%) increased significantly in both treatments over five months. Amounts of nutritive phagocytes (%) increased significantly only under invariant photoperiod while sizes (µm) of nutritive phagocytes increased in both photoperiod treatments but were significantly greater at invariant photoperiod. Amounts of gonial cells (%) increased significantly under ambient photoperiod. Oocyte feret diameters (µm) increased in both treatments but were largest at ambient photoperiod. Gonad (roe) taste was not appealing to taste testers. Therefore, seven diets of varying protein concentrations and the Wenger diet were fed to individuals maintained at invariant photoperiod for five months. This resulted in increased gonad indices in all diet treatments, but enhanced marketability of individuals for only three diets all of low/medium protein and high carbohydrate composition. Our results indicate that photoperiod manipulation and new diets can yield marketable sea urchin roe.

AN EXAMINATION OF THE BIOTIC AND ABIOTIC FACTORS INFLUENCING THE PARASITIC RELATIONSHIP OF A RHIZOCEPHALAN BARNACLE AND ITS HOST.

Emily Boone¹, Anne Boettcher², Tim Sherman², and Jack O'Brien². ¹University of Richmond, Department of Biology, Richmond, VA 23173. ²University of South Alabama, Biology Department, USCB 124, Mobile, AL 36688.

In the Gulf of Mexico and adjacent waters, the rhizocephalan barnacle *Loxothylacus texanus* parasitizes members of the genus *Callinectes*. However, factors affecting the distribution and prevalence of this parasite are not well understood. A series of studies have been conducted to determine what biological and physical factors influence this host-parasite relationship. *L. texanus* larvae are non-feeding and have approximately three days from metamorphosis to the cyprid stage for identification of a host, before their nutrient stores are depleted. During this time cypris larvae appear to be particularly sensitive to abiotic variations, including salinity fluctuations. The actual identification of a potential host appears to be mediated by chemical cues associated with the host, similar to those used by free-living barnacles. The female cypris larvae of *L. texanus* settle in response to carbohydrate or glycoprotein cues in the epicuticle layer of crab exoskeletons. Laboratory studies indicate, however, that successful settlement does not guarantee infection of the host. Results suggest that infection rates may be limited by factors such as host size, carapace content or immune response.

MYTELLA CHARRUANA ALONG THE ATLANTIC COAST OF FLORIDA: A SUCCESSFUL INVASION? Michelle Boudreaux, Nancy Gillis and Dr. Linda Walters. University of Central Florida.

Biological invasions are recognized as one of the most serious problems confronting the integrity of native species and ecosystems around the world. Unfortunately, invaders often go unnoticed until they have spread extensively, making eradication difficult and very costly. Early detection and rapid response to invasions are vital to prevent potential evolutionary and ecological changes that damage both our ecosystems and our economy. *Mytella charruana*, a tropical mussel native to Mexico and South America, first appeared in the intake pipes of a Jacksonville, Florida power plant in 1986. Fortunately, they never became established as the founder population was extirpated the winter of 1987, presumably due to cold temperatures. No new sightings of this species were recorded until 2004. Then, a population of *M. charruana* was discovered in Mosquito Lagoon, Florida (170 km south of Jacksonville) in August 2004. Since then the area has been surveyed monthly for mussel occurrences. Specimens were found August 2004–February 2005 on manmade debris, driftwood and living oysters. No individuals were found again until August 2005. If ecological conditions are optimal for continued survival and establishment of *M. charruana*, this species has the potential to reproduce and out-

compete native mussels and declining oyster populations of the area. Our goal is to better understand this invasive before this happens. Rapid actions are needed to prevent *M. charruana* from having the economic and ecological impacts of the zebra mussel *Dreissena polymorpha* and green mussel *Perna viridis*.

SPATIAL COMPETITION BETWEEN OYSTERS AND BARNACLES IN A FLORIDA ESTUARY. Michelle Boudreaux and Dr. Linda Walters. University of Central Florida.

Populations of *Crassostrea virginica* within Mosquito Lagoon, Florida have recently undergone significant die-offs. Before effective restoration protocols can be established, important questions about the ecology of these oysters must be answered. My research focused on interactions between oysters and spatial competitors that may affect the settlement, growth, and survival of *C. virginica*.

I collected species inventory data for one year using lift nets to determine the sessile species present. Barnacles (*Balanus amphitrite* and *B. eburneus*) were the most abundant competitors. To determine if *Balanus* spp. were always in competition with oysters, shells from historic shell middens were examined. Results show that there has been a five fold increase in barnacle abundance per oyster shell and appearance of an invasive barnacle, *B. amphitrite*, since midden shells. Thus, spatial competition between barnacles and oysters has increased in Mosquito Lagoon.

To determine how *Balanus* spp. affected settlement, growth, and survivorship of *C. virginica*, experiments were conducted in which densities of *B.s amphitrite* and *B. eburneus* were manipulated on disarticulated oyster shells. Density treatments included: no barnacles (control), low, medium, and high coverage of barnacles. Laboratory settlement trials with oyster larvae were run with all shell treatments. Settlement was counted by microscopy. Treatments with oyster spat were deployed in the field to follow oyster growth and survivorship over 4 weeks. Settlement, growth, and survivorship of oysters were all affected by the presence of barnacles even in low densities. The specific *Balanus* spp. did not have an effect on oyster settlement, growth, or survivorship.

JUVENILE RECRUITMENT DYNAMICS OF THE PINTO ABALONE (*HALIOTIS KAMTSCHATKANA*) IN THE SAN JUAN ISLAND ARCHIPELAGO, WASHINGTON. Joshua V. Bouma¹, C. Jackels¹, K. M. Straus¹, B. Vadopalas¹, C. S. Friedman¹ and D. P. Rothaus². ¹University of Washington, School of Aquatic and Fishery Science, Box 355020, Seattle, WA 98195. ²Washington Department of Fish and Wildlife.

Research has shown that adult pinto (northern) abalone (*Haliotis kamtschatkana*) are in serious decline, prompting designation as a Threatened Species (Canada) and a Species of Concern (Washington State; U.S.). These declines may be due to recruitment failure; thus more information is needed about the life history of this species, especially larval and juvenile stages. We deployed

60 abalone recruitment modules (ARMs) previously shown to successfully attract juvenile abalone less than 50 mm shell length in the wild, at two depths and three sites in the San Juan Island archipelago (SJI) with historically significant abalone populations. All ARMs were surveyed *in situ* for juvenile abundance three times over the course of 15 months. No juvenile abalone were observed, although the ARMs were successful in attracting adult abalone and other juvenile invertebrate and fish species. The lack of juvenile abalone in the ARMs may be due to Allee effects or, in the northern SJI, to elevated temperatures and lowered salinities observed from the Fraser River summer plume. To test the latter hypothesis, a 3×3 full factorial experiment was implemented to examine the influence of environmentally relevant temperature (11°C, 16°C, and 21°C) and salinity (14 ppt, 23 ppt and 32 ppt) combinations on post-larval (3–7 mm) pinto abalone survival. By day three of the experiment 100% mortality was observed in all 14 ppt treatment groups regardless of temperature. Mortalities in each of the remaining temperature/salinity combinations over the 14 day study were not significantly different than controls, suggesting intolerance to low salinity in this species.

FOULING IN SCALLOP CULTIVATION: SOME ISLE OF MAN EXPERIENCES. Andrew R. Brand and Katherine A. Ross. Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man, IM96JA, UK.

Fouling of scallop shells and cultivation nets by living organisms can reduce scallop growth and is costly to remove. We examined the effects of fouling on physiochemical and food conditions inside pearl nets used for suspended culture of the great scallop (*Pecten maximus*) in the Irish Sea, off the Isle of Man, and also investigated biological control of fouling using a range of invertebrates. Fouling of nets reduced water movement but, contrary to common assumptions, did not reduce the quantity or the quality of food particles available for scallops. Other negative effects of fouling, such as accumulation of inorganic matter, nitrate and ammonia, were also absent. We concluded that the negative effects of fouling found in some previous studies may have been caused by foulers parasitizing or mechanically interfering with scallops, rather than creating an unfavourable environment. The biological control trials found that sea urchins (*Echinus esculentus* and *Psammechinus miliaris*) and hermit crabs (*Pagurus* sp.) removed fouling from nets more efficiently than other invertebrates. In our short-term experiments only *P. miliaris* was associated with increased scallop shell growth, but no biological control organism reduced scallop growth or survival. These results suggest that biological control could be an efficient and environmentally sound method of dealing with the problem of fouling in scallop cultivation.

CRASSOSTREA ARIAKENSIS AND C. VIRGINICA RESPONSES TO ICHTHYOTOXIC KARLODINIUM VENEFICUM. E. F. Brownlee¹, A. R. Place², H. Nonogaki², J. E. Adolf², S. G. Sellner³ and K. G. Sellner⁴. ¹Calvert High School, ²Center for Marine Biotechnology, University of Maryland, ³Morgan State Environmental Research Center, ⁴Chesapeake Research Consortium.

The Eastern oyster, *Crassostrea virginica*, and the Asian oyster, *C. ariakensis*, are native and potentially introduced oysters, respectively, in the Chesapeake Bay and as such, will be exposed to the natural phytoplankton assemblages including harmful species throughout their life cycles. Recent work suggests that at least one of these prey items, the ichthyotoxic dinoflagellate *Karlodinium veneficum*, occurs frequently throughout the growth period for the oysters, thereby insuring frequent exposures for all life stages of the bivalve. *K. veneficum* produces linear polyketide toxins (karlotoxins), which elicit toxicity through sterol-dependent, non-specific pores in biological membranes. Spat and juvenile oysters of each species were exposed to a moderately toxic level [18.5 ± 6.2 ng ml⁻¹] of the dinoflagellate at environmentally-relevant cell densities and growth contrasted with rates observed on other phytoplankton species, including the spring bloom former *Prorocentrum minimum* and a phytoplankton mixture routinely used in oyster hatcheries. Growth for spat and juveniles of both oysters was significantly reduced when feeding on *K. veneficum*, relative to the other prey species. Experiments are continuing to identify the importance of food quality versus toxin content in oyster responses. These initial results suggest that the cosmopolitan *K. veneficum* inhibits growth and would potentially curtail oyster production within the tidal Bay and its tributaries throughout the oysters' growth periods and considering its global distribution, potential impact throughout temperate areas should be assessed.

FILTRATION CAPACITY AS A WAY TO SCALE RESTORATION OBJECTIVES: AN EXAMPLE FROM CHESAPEAKE BAY. Robert D. Brumbaugh¹ and A. Thomas Leggett Jr.² ¹The Nature Conservancy Global Marine Initiative, URI Narragansett Bay Campus, South Ferry Rd., Narragansett, RI 02883. ²Chesapeake Bay Foundation.

The decline of eastern oyster populations in Chesapeake Bay and elsewhere in the species' range is well documented, and efforts are underway to develop and test restoration approaches. In addition to restoring lost fisheries productivity, ecosystem services are increasingly cited as a reason for restoration. Policy makers in the Chesapeake Bay region have adopted a bay-wide goal for oyster restoration (10% of historic abundance by 2010), but little guidance exists for forecasting exactly how much restoration effort will be necessary to achieve this goal. We used the Lynnhaven River, a small tidal tributary in the southern Chesapeake Bay, as a model

for both evaluating the efficacy of restoration approaches and developing scaling arguments for the larger Bay-wide restoration effort. Oyster restoration in the Lynnhaven began in 1998 and has entailed both reef habitat enhancement (~5.5 acres) and stock enhancement to increase recruitment rates. Oyster biomass, estimated from annual abundance surveys, was used to calculate a “filtration capacity” of restored reefs. We estimate that oysters on the restored reef area are capable of filtering a volume equivalent to the river’s volume every 63.5 days. This approach can be used to set restoration goals at scales ranging from tributaries to entire estuaries.

IMPACTS OF THE COLONIAL ASCIDIAN (*DIDEMNUM SP. A*) ON MUSSELS, OYSTERS AND SCALLOPS. Stephan G. Bullard¹, Robert B. Whitlatch², Richard W. Osman³ and Sandra E. Shumway². ¹University of Hartford, Hillyer College, 200 Bloomfield Ave., West Hartford, CT 06117. ²University of Connecticut. ³Smithsonian Environmental Research Center.

The carpet tunicate (*Didemnum sp. A*) is a colonial ascidian of unknown origin with rapidly expanding populations on the east and west coasts of North America. The carpet tunicate can grow on most natural and man-made hard substrata habitats (rocks, cobbles, docks, pilings, boat hulls). Large colonies form nearly solid mats that may smother benthic organisms. The carpet tunicate may be of particular concern for shellfish, and thus the aquaculture industry, as colonies can overgrow individual bivalves or completely cover material used to culture them. To determine the effect of the carpet tunicate on cultured juvenile shellfish, we deployed mussels (*Mytilus edulis*), oysters (*Crassostrea virginica*), and scallops (*Argopecten irradians*) in bags at 3.5 m depth with and without fragments of *Didemnum sp. A*. We assessed the survivorship, growth and condition index of shellfish after approximately one and two months of deployment. After one month, many shellfish in the treated bags had the ascidian growing on their shells; some were 100% covered. Preliminary data on survivorship, growth and condition index will be presented.

A MOLECULAR COMPARISON OF OYSTER HERPES VIRUSES FROM ASIA, EUROPE, AND NORTH AMERICA. Colleen A. Burge¹, Carolyn S. Friedman¹, Kimberly S. Reece², Jessica A. Moss² and Tristan Renault³. ¹University of Washington, School of Aquatic and Fishery Sciences, Seattle, WA 98195. ²Virginia Institute of Marine Science, ³IFREMER.

Oyster herpes viruses (OsHV) have been identified in multiple bivalve species globally. Some of these herpes viruses have been identified and described using molecular tools including Polymerase Chain Reaction (PCR), *in situ* hybridization (ISH), and nucleic acid sequencing. To date, PCR and sequence analysis have identified possible variants. One variant (OsHV-1) collected in France

was recently purified, sequenced, and morphologically characterized as a member of the family *Herpesviridae*. We have begun using PCR primer sets developed to amplify distinct regions of the OsHV-1 genome to identify possible sequence divergences in OsHV in oysters collected from two sites in China (*Crassostrea ariakensis*), one site in Japan (*C. gigas*), and one site in the United States (*C. gigas*) as compared to OsHV-1. Preliminary PCR results indicate that the OsHV identified in China and Japan is similar, but differs from OsHV-1, while samples collected in the United States are more comparable to OsHV-1. We plan to expand this analysis to include samples from sites in China and Korea where OsHV has been identified. We also plan to test additional primer sets and to sequence additional regions to better describe OsHV variants.

EASTERN OYSTER SETTLEMENT AND EARLY SURVIVAL ON ALTERNATIVE SUBSTRATES ALONG INTERTIDAL MARSH, RIP RAP, AND MANMADE OYSTER REEF. Russell Burke¹, Romuald Lipcius¹, Mark Luckenbach¹, P. G. Ross¹, Justine Woodward¹ and David Schulte². ¹Virginia Institute Marine Science: College of William & Mary, 1208 Greates Rd., Gloucester Point, VA 23062. ²Army Corps of Engineers—Norfolk, VA District.

Restoration efforts with native Eastern oyster, *Crassostrea virginica*, in Chesapeake Bay have been extensive and have been impeded by substrate and recruitment limitations along with many other detrimental factors. In Lynnhaven Bay, a southern subestuary of Chesapeake Bay, the Army Corps of Engineers has partnered with the Virginia Institute of Marine Science, National Oceanic and Atmospheric Administration, and Chesapeake Bay Foundation to implement a comprehensive oyster reef restoration strategy. Surveys within the Lynnhaven Bay system indicate that artificial oyster shell reefs created in the early 1990s are producing poor to marginal oyster densities relative to densities on nearby granite and concrete riprap, and on oyster clusters along marsh-fringed shores. In this field experiment, twelve treatments simulating inter-tidal oyster habitat were placed at three sites within a tidal creek: adjacent to marsh, rip rap and a manmade oyster reef. Treatments consisted of caged and uncaged trays (0.5 m length × 0.5 m width × 0.25 m depth) of large granite, small granite, large limestone marl, small limestone marl, very small concrete/granite, and oyster shells. Granite of both sizes had the highest initial oyster recruitment across all sites. Overall, replicates showed a distinct recruitment/early survival pattern between sites: marsh > rip rap > artificial oyster reef. We therefore propose that granite may be a favorable oyster reef construction material, since it appears to enhance oyster settlement and early post-settlement survival. Additional biological benefits may accrue from granite reefs as community structure develops on the reefs.

DIVERSITY AND DISTRIBUTION OF UNIONID BIVALVES IN TEXAS. Lyubov E. Burlakova¹, Alexander Y. Karatayev¹, Robert G. Howells² and Daniel L. Bennett¹. ¹Department of Biology, Stephen F. Austin State University, Box 13003—SFA Station, Nacogdoches, TX 75962-3003, ²Texas Parks and Wildlife Department, Ingram, TX.

The family *Unionidae* is one of the most rapidly vanishing faunal groups in North America, and habitat destruction is considered to be the most important cause for the decline. To evaluate the current status of unionid diversity in Texas we re-examined species composition and abundance of unionid in 30 waterbodies previously surveyed by the Texas Parks and Wildlife Department. The highest diversity was found in Sabine River (18 species), B. A. Steinhagen Reservoir (16), Neches River below Town Bluff Dam (14), Village Creek (14), and Sanders Creek (14). The lower San Marcos River and Guadalupe River (Central Texas) were found to support rare, endemic *Quadrula aurea*. Living rare endemic *Lampsilis bracteata* were found in Live Oak Creek, the Guadalupe River, and the San Saba River (Central Texas). Rare species of *Fusconaia* (*F. askewi* and endemic to Texas *F. lananensis*) are still present in Attoyac Bayou and Sandy Creek, and in Village Creek in Big Thicket National Preserve (East Texas). In addition, this latter creek continues to support rare *Pleurobema riddelli*. Several large reservoirs surveyed had drought- and drawdown-related low waters in recent years that presumably caused reductions in mussel abundance and diversity.

CHANNELED-TYPE APPLESNAILS: CURRENT DISTRIBUTION, DENSITIES AND POTENTIAL THREAT TO NATURAL ECOSYSTEMS AND AGRICULTURE. Lyubov E. Burlakova, Alexander Y. Karatayev, David N. Hollas and Leah D. Cartwright. Department of Biology, Stephen F. Austin State University, Box 13003—SFA Station, Nacogdoches, TX 75962-3003.

The aquatic invasive gastropod *Pomacea canaliculata* (channeled applesnail), originally from South America, has become a major pest of rice crops throughout the Indo-Pacific Region. These large herbivorous snails can reach maturity in about two months during the summer, reproduce several times a month, and aestivate for several months, burying into the soil if the habitat dries out. By mid 2005, living populations of channeled-type applesnails were reported from Florida, Texas, California, Alabama, Arizona, and Georgia. According to the results of genetic analyses, specimens from Texas and Florida belong to the *P. canaliculata*-group. The first reproductive applesnail population in Texas was reported in 1989, and by the summer of 2005 snails were found in six south-eastern counties (Harris, Chambers, Brazoria, Galveston, Fort Bend, and Waller). Reproduction of channeled-type applesnails in Texas continues for at least 8 months, from March to the beginning of November. Densities of snails in Texas vary depending on waterbody type and possibly presence of predators. The rice grow-

ing technology used in Texas combined with current low densities of snails are the likely reasons why agricultural damage due to applesnails has not yet been detected.

OYSTER SEX WARS: EVIDENCE FOR A 'GAMETE SINK' IF *CRASSOSTREA VIRGINICA* AND *CRASSOSTREA ARIAKENSIS* SPAWN SYNCHRONOUSLY. David Bushek, Andrea Kornbluh, Greg Debrosse, Haiyan Wang, Ximing Guo and John Quinlan. Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers, The State University of New Jersey, 6959 Miller Avenue, Port Norris, NJ 08349 USA.

Available data indicate spawning seasons for the Asian oyster *Crassostrea ariakensis* and the eastern oyster *C. virginica* overlap. Hybrids can form, but the larvae are not viable. If *C. ariakensis* are introduced into Chesapeake Bay and synchronous spawning occurs with *C. virginica*, hybridization could reduce the production of viable larvae (= gamete sink). We examined the effects of gamete age, sperm concentration, and ratios of heterospecific gametes on fertilization rate and hybridization of the two species. Hybrid fertilization rates were consistently lower than pure crosses. Fertilization rate decayed with gamete age, but occurred in gametes up to eight hours old. Fertilization rate also decayed with decreasing sperm density in both pure and hybrid crosses. Finally, fertilization rate declined by as much as 60% when sperm were (1) given a choice of eggs from each species to fertilize or (2) required to compete to fertilize eggs from a single species. Hence, a gamete sink will likely occur if these two species spawn synchronously. The magnitude of the gamete sink will depend in part on proximity of the two species, on gamete concentrations in the water column, and on the proportion of hybrids that form. Current efforts are enumerating the proportion of hybridization that occurred during these experiments. Molecular genetic methods to amplify ITS regions of the rRNA gene have been validated and yield two bands in pure crosses and four bands in hybrid crosses. Individual larvae are being typed to determine the proportion of hybrids formed under the various gamete mixtures.

ESTIMATION OF RECREATIONAL DUNGENESS CRAB HARVEST IN PUGET SOUND, WASHINGTON USING A TELEPHONE SURVEY OF HARVESTERS. Jennifer Cahalan. Washington Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, 1000 Point Whitney Road, Brinnow, WA 98320.

The recreational Dungeness crab harvest in Puget Sound exceeds 1.5 million pounds of crab annually. In order to meet fisheries management decision-making needs, estimates of recreational Dungeness crab harvest need to be precise and accurate, provided for relatively small geographic and temporal scales, and

available during the recreational season. The recreational Dungeness crab fishery is characterized by relatively low effort dispersed over a large geographic area. As a result field-based methods of estimating recreational catch were inefficient and expensive. Alternate methods of estimating catch were developed and implemented in 2002.

To fish for crab in Washington State, crab harvesters are required to obtain a catch record card (CRC) from the WDFW. A telephone survey of CRC-holders is used to collect the data used in catch estimation. Catch estimates are generated approximately three to four weeks after the survey begins for each of Puget Sound's 11 catch areas. A minimum of two surveys are conducted each season. This method provides timely in-season estimates of harvest at relatively low cost. In this presentation, the details of the methods will be discussed, including treatment of missing data, precision of estimates, cost, and potential improvements.

INBREEDING EFFECTS ON GROWTH AND SURVIVAL IN A NATURALIZED POPULATION OF THE PACIFIC OYSTER (*CRASSOSTREA GIGAS*) REVEALED USING MARKER BASED RELATEDNESS ESTIMATES. Mark D. Camara¹, Sanford Evans², and Chris Langdon². ¹USDA—Agricultural Research Service, 2030 SE Marine Science Dr., Newport, OR 97365, ²Molluscan Broodstock Program, Newport, Oregon USA.

Inbreeding is an important factor influencing mating systems, dispersal mechanisms, and variation in life history traits within and among populations and thus has profound implications in evolutionary biology, selective breeding, conservation biology, and even medicine. In theory, high fecundity species, such as elm trees and oysters, are expected to have higher genetic load and consequently more severe inbreeding depression than low fecundity species, and previous studies have confirmed that self-fertilization, brother/sister matings, and cousin/cousin matings in *C. gigas* produce progeny with lower growth and survival than non-consanguineous pairings of parents. It is unclear, however, whether these effects can be extrapolated to the lower levels of consanguinity expected in natural populations with random mating. We studied inbreeding in a naturalized population of Pacific oysters using three molecular marker-based estimates of parental relatedness calculated from multi-locus microsatellite genotypes. Using analysis of covariance approaches, we found significant relationships between estimators of parental genetic similarity and components of fitness. As expected, more highly related parents produced progeny with lower survival (i.e. inbreeding depression). Surprisingly, however, the surviving progeny of genetically similar parents had higher growth (outbreeding depression or heterosis) than less related parental pairs. We discuss potential mechanism underlying these patterns and their implications for aquaculture and selective breeding.

HAEMOLYMPH PROTEOMIC APPROACH TO ANALYSE DIFFERENCES IN SUSCEPTIBILITY TO BONAMIOSIS BETWEEN OYSTER STOCKS. Asunción Cao, José Fuentes and Antonio Villalba. Centro de Investigacións Mariñas, Xunta de Galicia, P.O. Box 13, 36620 Vilanova de Arousa, Spain.

The parasitic protozoan, *Bonamia ostreae*, causes oyster, *Ostrea edulis*, mass mortalities throughout the European Atlantic coast. The parasite is phagocytosed by oyster haemocytes but is not killed. The parasite divides in haemocyte cytoplasm causing the rupture of the host cell. Differences in susceptibility to bonamiosis between *O. edulis* stocks have been verified. Furthermore, the oyster *Crassostrea gigas* is resistant to bonamiosis. Separation of the proteins of oyster haemolymph by two-dimensional electrophoresis was tuned up resulting in multiple proteic spots on polyacrilamide gels. This proteomic approach is being applied to analyse differences in susceptibility to bonamiosis between *O. edulis* stocks and between *O. edulis* and *C. gigas*. The *O. edulis* stocks used in the comparisons are: Rossmore (strain selected for resistance against bonamiosis), oysters from Tralee Bay (Ireland) where the parasite had not previously been detected, and oysters from Ría de Ortigueira (Galician, NW Spain) where *B. ostreae* is present since early 1980s. Comparison between infected and uninfected oysters is also included. Application of specific commercial software makes easy qualitative and quantitative comparison between gels corresponding to haemolymph of each oyster group. Early results have shown spots exclusive of each group and other spots that are common to every oyster group. Identification of the proteins in the spots could contribute to explain differences in susceptibility and even provide the key for resistance to bonamiosis.

POTENTIAL IMPACT OF *BONAMIA* SP. ON *CRASSOSTREA ARIAKENSIS* IN CHESAPEAKE BAY AND NORTH CAROLINA. Ryan B. Carnegie¹, Nancy A. Stokes¹, Corinne Audemard¹, Eugene M. Burreson¹, Melanie J. Bishop², Charles H. Peterson³, Ami E. Wilbur³, Troy D. Alphin⁴ and Martin H. Posey⁴. ¹Virginia Institute of Marine Science, ²University of North Carolina Institute of Marine Sciences, ³UNC Wilmington Center for Marine Sciences, ⁴UNC Wilmington Dept. of Biology and Marine Biology.

A *Bonamia* sp. emerged in 2003 as the cause of mortality (>85%) among experimental seed *C. ariakensis* in Bogue Sound, North Carolina. With introduction of this oyster to Chesapeake Bay proposed, this epizootic gave urgency to investigations into the nature of bonamiasis in the mid-Atlantic; its annual timing and range, environmental limitations, and the identity and distribution of parasite reservoirs. Field studies included *Bonamia* sp. monitoring in *C. ariakensis* deployments along a salinity gradient from Bogue Sound, and at distant coastal sites; in serial deployments of seed *C. ariakensis* to upwellers on Bogue Sound; and among *Ostrea equestris* from Bogue Sound and Wilmington, NC. Labo-

ratory trials have explored effects of reduced salinity on existing *Bonamia* sp. infections. Epizootics recurred in 2004–2005, generating infections for laboratory use and allowing an initial portrait of *Bonamia* sp. to be developed. This parasite causes acute disease and mortality in smaller/younger *C. ariakensis* (<40 mm) in higher salinity coastal waters during warmer months. Infections may regress in winter. It is known to occur only at Bogue Sound and Wilmington, >100 km to the southwest. It occurs in *O. equestris* in both places, but this oyster may not be a functional reservoir for *Bonamia* sp., or its only other host. In the laboratory, infections were purged at 20 and 10 psu, further suggesting that lower estuarine salinities (such as in Pamlico Sound, where *Bonamia* sp. has been notably absent from a mesohaline *C. ariakensis* nursery site, or Chesapeake Bay) may limit *Bonamia* sp. activity.

DEVELOPING STRATEGIES TO REDUCE THE IMPACT OF THE BORING SPONGE *CLIONA CELATA* ON CULTURED EASTERN OYSTERS *CRASSOSTREA VIRGINICA*.

Claire Carver and André Mallet. Mallet Research Services, 4 Columbo Dr., Dartmouth, Nova Scotia, Canada B2X 3H3.

It has long been recognized that the boring sponge (*Cliona celata*) can cause significant economic losses to those involved in the harvesting of wild oyster populations. It is not clear, however, whether the presence of a boring sponge population may act as a source of infection to cultured oysters grown in floating bags or on oyster tables. Preliminary surveys conducted in one bay in northern New Brunswick, Canada, suggested that in some areas 35% of the off-bottom cultured oysters showed evidence of shell degradation associated with boring sponge infection. The development of strategies to mitigate the impact of this organism is hampered by the lack of basic information on growth rates, spawning activity, and modes of infection. We report on the preliminary results from an ongoing multi-year project to document the life-history characteristics of this biofouling species and evaluate the effectiveness of various treatment strategies.

PREVALENCE AND GEOGRAPHIC DISTRIBUTION OF A DUNGENESS CRAB (*CANCER MAGISTER*) MICROSPORIDIAN PARASITE. Richard K. Childers¹, Paul W. Reno² and Robert E. Olson². ¹Washington Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, 1000 Point Whitney Rd., Brinnon, WA 98320, ²Oregon State University, Hatfield Marine Science Center.

The prevalence and geographic distribution of *Nadelspora canceri* a microsporidian parasite of the Dungeness crab *Cancer magister*, was studied and prevalences were analyzed by sex and size of host and date of collection. *N. canceri* was widely distributed along the United States Pacific Coast in estuaries from Bodega Bay, California to southern Washington. Prevalence of the parasite

was high in crabs from most estuaries sampled between 1991 and 1994, ranging from a low of 0.4% (Gray's Harbor, Washington) to 41.2% (Tillamook Bay, Oregon) with an overall mean of 14%. Crab examined from Grays Harbor between 2002 and 2004 indicate the prevalence rate had increased from 0.4% to greater than 14%. The parasite also occurred offshore of California and Oregon, but was not found in Puget Sound, Washington or in Glacier Bay, Alaska. The prevalence of infection in crabs captured in the open ocean was low (0.3%). In crabs collected nearshore at estuary mouths prevalence was intermediate between estuarine and open-ocean levels. The infection was most prevalent in two year old crabs (13 cm carapace width), and males had 2.5 times the rate of infection than did females.

The mortality of laboratory-held crabs naturally infected with *N. canceri* was compared to that of uninfected crabs and significantly higher mortality was observed for infected crabs. *N. canceri* infections were established in juvenile and adult crabs that were fed parasite spores in laboratory experiments indicating that transmission is direct and intermediate hosts or vectors are not required for transmission.

HABITAT ATTRIBUTES ASSOCIATED WITH BAY SCALLOPS IN AN AREA WITH ACTIVE RESTORATION. Mar-nita M. Chintala¹, Eric J. Weissberger¹, David W. Grunden², Elizabeth Hinchey³, William G. Nelson⁴, Russell Ahlgren¹ and Michael Charpentier⁴. ¹U.S. EPA, ORD/NHEERL, Atlantic Ecology Division, ²Town of Oak Bluffs, MA, ³Illinois-Indiana Sea Grant, Purdue University, ⁴CSC Corporation, Narragansett, RI.

Habitat quality and quantity are important factors to maintain bay scallop (*Argopecten irradians*) populations, however, data linking habitat attributes to bay scallop populations are lacking. This information is essential to relate habitat alteration to the decline of bay scallop populations and to guide restoration efforts to reverse declines. Initial results of 30 dive surveys conducted in September 2005 in Lagoon Pond, Martha's Vineyard, MA, (538 acres) indicate a correlation between scallop abundance and total plant cover (macroalgae and eelgrass combined), depth, and sediment type. Scallop abundance was highest (15.42 scallops m⁻²) at a site where average total plant cover was 24%. Most scallops were found in shallower areas (depth 1–5 m) along the edge of Lagoon Pond, with deeper, unvegetated, sites devoid of scallops. Shell height (measured from umbo to opposite edge) ranged from 10 to 90 mm, with larger scallops present in the northern and eastern pond areas. Height distribution was primarily unimodal; however, a few locations had bimodal distributions. Scallop abundance will be related to restoration methods (e.g., seeding, spat bags) in the pond to assess how these activities have influenced the relationship between bay scallops and habitat.

EFFECTS OF TRICLOSAN ON THE OYSTER PARASITE, *PERKINSUS MARINUS* AND ITS HOST, THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*: A COMPARISON AT DIFFERENT TEMPERATURES. Fu-Lin E. Chu, Eric D. Lund, and Jennifer A. Littell. Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA.

While causing minimal effect on oyster hemocyte viability, our previous study showed that the antibiotic, triclosan, not only inhibits growth and greatly reduces the viability of *in vitro* cultured *Perkinsus marinus* meronts, the primary disease transmission stage, but also inhibits the parasite's fatty acid synthetic ability. Due to the great importance of temperature on disease progression in the field, we tested the effects of triclosan on the viability of *P. marinus* meronts and oyster hemocytes at high and low temperatures. Parasite or oyster hemocytes were exposed to triclosan (0, 2, 5, or 10 μ M) for 24 hr and then their viabilities were assessed by MTS/PMS assay. Exposure of *P. marinus* meronts to 2, 5, or 10 μ M triclosan at 20, 26 and 28°C significantly reduced their viability (40–60%). At 13°C, *P. meronts* had a better triclosan tolerance, with viabilities of 67–73%. Oyster hemocytes treated with triclosan exhibited less than 10% mortalities at triclosan concentrations of ≤ 10 μ M at 13°C. Hemocytes viabilities reduced slightly (10–16%) at 5 and 10 μ M triclosan exposure. No significant reduction (≤ 0.05) in viability relative to the controls occurred in hemocytes at triclosan concentrations from 2 to 10 μ M at 26°C. However, exposure of hemocytes to triclosan at 28°C, reduced viability to less than 63% at a concentration of 10 μ M. Triclosan exposure did not appear to affect reactive oxidative intermediate production in zymosan-stimulated and unstimulated hemocytes. This study is supported by a grant from the Oyster Disease Research Program (Grant # V710720), Sea Grant, NOAA.

SC'S COMPREHENSIVE INTERTIDAL OYSTER ASSESSMENT USING HIGH RESOLUTION IMAGERY FOR MANAGEMENT AND RESTORATION. L. D. Coen¹, K. E. Schulte¹, G. M. Yianopoulos², R. F. Van Dolah¹, W. D. Anderson², M. A. Finkbeiner³ and W. R. Stevenson³. ¹MRRI, SCDNR, 217 Fort Johnson Rd., Charleston, SC 29912, ²OFM, SCDNR, ³NOAA Coastal Services Center.

SCDNR is currently undertaking a state-wide assessment of its oyster resources as part of a multi-year, collaborative effort with NOAA's Coastal Services Center (CSC) and the U.S. Geological Survey. Using a previously developed approach for analyzing multispectral ¼ m digital imagery, we are processing the finalized imagery (digital orthophoto quarter quads) using Feature Analyst® and ERDAS's Imagine® to derive oyster reef location (presence-absence), areal extent and proportion of vertical shell coverage within a bed's boundaries. Two teams randomly survey portions of 60 DOQQs using shallow draft boats at or near MLW for verifi-

cation of the processed imagery. Field efforts also utilize Trimble Pathfinder Pro XR™ surveying units to measure reef length and position, as well as to note oyster density ('strata') and average reef width. Real-time Digital8™ video is recorded for each reef and is post-processed to determine estimates of percent vertical oyster coverage in defined time segments. Helicopter flights are also used for inaccessible areas. Post-processed imagery is validated by identifying beds that are correctly and incorrectly identified at a predefined accuracy level. This project will allow us to: (1) complete future evaluations by periodically re-flying and reassessing the state's shellfish beds; (2) provide both SCDNR and other interested users with detailed imagery available for a manifold of other uses; and (3) focus our oyster bed restoration efforts relative to current state management plans and status and trends analyses.

APPROACHES TO SMALL-SCALE OYSTER RESTORATION: SITE CRITERIA AS A MEANS OF DETERMINING OPTIMAL METHODS FOR PUBLIC INVOLVEMENT. Loren D. Coen¹, Rob Brumbaugh² and Nancy H. Hadley¹. ¹Marine Resources Research Institute, 217 Fort Johnson Rd., Charleston, SC 29912, SCDNR, ²The Nature Conservancy, Global Marine Initiative.

Crassostrea virginica reefs were once a dominant feature of most Atlantic and Gulf coast estuaries, but have drastically declined in many areas across the U.S. Once valued primarily as a fishery resource, oysters are now recognized as key elements of many estuarine ecosystems, with a diverse set of attendant ecosystem services. Large- and small-scale restoration of subtidal and intertidal oyster habitats is ongoing in most Atlantic and Gulf coast states. For small-scale community-based restoration projects, an array of restoration approaches are in use, each of which has relative merits and limitations. Examples of these approaches include oyster gardening for stock enhancement, deployment of pre-filled oyster shell bags for intertidal restoration, and community-based shell recycling. We discuss the characteristics of these approaches, as well as several other deployment methods under consideration, and examine the logistical benefits and limitations of each. We also identify specific site criteria such as recruitment or substrate limitation that may be useful for identifying the most appropriate methodology for practitioners to employ in small-scale restoration projects.

MOLECULAR GENETIC VARIATION AMONG QPX ISOLATES. Jackie L. Collier, Hua Qian, Qianqian Liu and Bassem Allam. Discovery 145, Marine Sciences Research Center, Stony Brook University, Stony Brook, NY 11794-5000.

QPX has caused significant mortality of hard clams, *Merccenaria mercenaria*, in many locations along the east coast of North America since the 1960's, and a new outbreak of QPX occurred in

Raritan Bay NY during the summer of 2002. We have cultured new isolates of QPX from Raritan Bay clams collected in 2003 and 2004 and are using them, along with the Massachusetts isolate ATCC50749 and new Massachusetts QPX cultures isolated in 2005, to investigate the molecular genetic variability within QPX. We have found no sequence variability in the 18S and 5.8S rRNA genes from 6 New York isolates and ATCC50749. In contrast, the rRNA operon intergenic transcribed spacers, ITS1 and ITS2, showed a great deal of variability. Interestingly, the variation among ITS1 and ITS2 sequences from a single isolate was as great as the variability among the eight QPX isolates examined (seven from NY and ATCC50749). This result shows that the many copies of the rRNA operon in the QPX genome are not homogenized by gene conversion quickly enough to overcome the accumulation of sequence variation, and may suggest that QPX reproduces predominantly asexually. Sequences of 4 mitochondrial protein-coding genes also showed no sequence variability within or between the four isolates (two from NY and two from MA) examined. We will also present data from our current efforts to sequence non-coding regions of the mitochondrial genome.

PERKINSUS MARINUS INFECTION IN OYSTERS FROM SOUTHEASTERN NORTH CAROLINA TIDAL CREEKS WITH VARYING WATER QUALITY. Sara L. Colosimo, Martin H. Posey and Troy D. Alphin. University of North Carolina Wilmington—Center for Marine Science, 5600 Marvin K. Moss Lane, Wilmington, NC 28504.

On the East coast of the United States, oysters represent a critical fishery and impact many ecosystem functions, affecting water quality and providing habitat for a variety of fish and invertebrates. However, the Eastern oyster, *Crassostrea virginica*, has experienced major mortality throughout its range; attributed in part to disease caused by the protozoan parasite *Perkinsus marinus* (Dermo). This mortality has not been as severe for intertidal oyster populations in southeastern North Carolina as it has been in other areas. Anthropogenic stressors associated with storm water runoff, such as non-point source nutrient inputs and suspended particulates, may contribute to declining water quality and affect infection rates. Exposure to such environmental stressors can adversely affect oysters and increase their vulnerability to infection. This study compares *P. marinus* infection levels in oysters from three southeastern North Carolina tidal creeks that vary in water quality characteristics. Prevalence and intensity of *P. marinus* infection are being compared among creeks for both natural oyster populations and hatchery stock outplants using RFTM tissue assay. Data on growth, condition index, and mortality are also being compared. We predict that oysters in creeks with higher levels of nutrient inputs and particulates will have higher prevalence and intensity of infection. Preliminary results indicate that infection levels for all three creeks appear to be similar. For each creek, average infection intensity is light and infection is nearly 100% prevalent. Despite

low overall infection intensities, hatchery oysters in each creek have an average mortality of 20%.

CHARACTERIZATION OF BAC LIBRARIES FROM THE OYSTERS *CRASSOSTREA VIRGINICA* AND *C. GIGAS*.

Charles Cunningham¹, Junichi Hikima¹, Robert Chapman¹, Matthew J. Jenny¹, Jeff Tomkins² and Greg W. Warr¹. ¹Hollings Marine Laboratory, Charleston, SC29412. ²Clemson University Genomics Institute, Clemson, SC 29634.

BAC libraries of two commercially and economically important species, *C. virginica* and *C. gigas*, have been developed as part of an international effort (co-ordinated by the Oyster Genome Consortium) to develop tools and reagents that will advance our ability to conduct genetic and genomic research on oysters. A total of 73,728 *C. gigas* clones with an average insert size of 150 kb were picked and arrayed representing approximately 12-fold genome coverage. A total of 55,296 clones with an average insert size of 134 kb were picked and arrayed for *C. virginica* representing approximately 10-fold coverage. The *C. gigas* and *C. virginica* libraries were screened with probes derived from 13 and 14 randomly selected genes respectively. All of the probes tested detected multiple clones ranging from 8–25 clones for *C. virginica* and 5–50 for *C. gigas*. These numbers suggest that there is no gross bias in either library and that some of the genes probed are members of multi-gene families. We have conducted a preliminary analysis of polymorphism represented in the two libraries using gene-specific primers for PCR amplification and nucleotide sequencing from selected BAC clones. Results suggest that the degree of sequence difference between alleles is highly variable (in a gene-specific manner) and that variability is, as would be predicted, concentrated in intronic regions.

DESIGN AND CHARACTERIZATION OF A MULTI-SPECIES OYSTER CDNA MICROARRAY.

Charlie Cunningham¹, Matt Jenny², Robert Chapman³, Gregory Warr¹, Jonas Almeida⁴, Ann Chen⁴, Dave Mckillen⁴ and Hal Trent⁴. ¹University of New Mexico. ²Woods Hole Oceanographic Institute. ³South Carolina Department of Natural Resources. ⁴Medical University of South Carolina.

The eastern oyster, *Crassostrea virginica*, and the Pacific oyster, *C. gigas*, are important economic resources from both the harvesting of natural populations and aquaculture industry. In addition, because of their vital role in estuarine ecosystems oysters are a valuable model organism for environmental research. In an effort to increase our understanding of the effects of environmental pressures and disease on oyster physiology and health, an international collaboration (the Oyster Microarray Consortium) was initiated to construct a multi-species cDNA microarray consisting of expressed sequence tags from *C. virginica*, *C. gigas*, and the oyster pathogen *Perkinsus marinus*. The microarray consists of 4,460

clones from *C. virginica*, 2,320 clones from *C. gigas*, and 384 clones from the oyster pathogen, *P. marinus*. Functional annotation of the oyster clones was performed by comparison to the Gene Ontology database. As part of the initial characterization of this array, tissue specific signatures were identified by gene expression profiling both gill and hepatopancreas tissues from both species of oyster. Hepatopancreas gene expression profiles were also obtained from *C. ariakensis*, an oyster species not represented by clones on the array. The utility of the microarray for comparative studies between multiple oyster species was determined by the analysis of several hundred clones demonstrating cross-hybridization potential. Correlations between hybridization intensity and sequence homology of several hundred clones were used to estimate the level of sequence identity necessary for sufficient cross-hybridization. Results demonstrate the benefits in gene expression profiling by having multiple genes from both oyster species present on the array.

EXPRESSION ANALYSIS OF CANDIDATE LOCI FOR GROWTH HETEROSIS IN THE PACIFIC OYSTER. Jason Curole, University of Southern California.

The Pacific oyster has emerged as a model system to understand the genetic and physiological mechanisms of growth heterosis. A set of candidate loci for growth heterosis has been identified through comparative transcriptomic analysis of hybrid and inbred 6-day old oyster larvae. Evaluation of candidate loci requires discovery of polymorphisms, genetic mapping, and detailed analysis of expression patterns. *Crassostrea gigas* has a high density of single nucleotide polymorphisms and a surprisingly high density of indels (Curole & Hedgecock 2005, http://www.intl-pag.org/13/abstracts/PAG13_W026.html). Using size fragment analysis to detect indel differences between parental alleles, I have genotyped eight of these candidates in a phenotyped F_2 population. In addition, I have examined expression at several candidate loci in an F_1 population and identified SNPs in this population for analysis of allele-specific expression.

BIOENERGETICS OF JUVENILE PINK ABALONE FED FORMULATED DIETS CONTAINING DIFFERENT LEVELS OF PROTEIN AND STARCH: LIPID RATIOS. Louis R. D'Abramo¹, Jessica Montano-Vargas², Armando Shimada³, Carlos-Vasquez-Pelaez³ and Maria Teresa Viana². ¹Department of Wildlife and Fisheries, Mississippi State University, ²Universidad Autonoma de Baja California, ³Universidad Nacional Autonoma de Mexico.

Juvenile pink abalone, *Haliotis corrugata*, (0.15 g) were grown for 131 days under laboratory conditions in aerated flow through seawater systems and fed semi-purified diets containing three different levels of protein, each level containing two ranges of starch lipid ratios (1.5 to 1.87 and 3.2 to 3.6), and similar gross energy

levels. Growth responses suggested a dietary protein requirement of approximately 35% with carbohydrate being the principal source of energy (high starch to lipid ratios). Optimum dietary lipid levels appear to be principally based on the satisfaction of specific nutrient requirements. Ammonia excretion ($\mu\text{g NH}_4^+ \text{h}^{-1} \text{g}^{-1}$) ranged from 7.9 to 4.8 but was not significantly different among dietary treatments, except for the treatment containing 32% crude protein and a low carbohydrate: lipid ratio. Energy lost due to mucus production did not significantly differ among dietary treatments. Specific dynamic action comprised nearly 50% of the measured oxygen consumption ($\mu\text{L O}_2 \text{h}^{-1} \text{g}^{-1}$) and did not differ significantly among dietary treatments. Respiration increased during the evening, suggesting a circadian pattern that is typical of the *Haliotis* genera. Approximately 70% of the ingested energy was lost to feces, and 25% metabolized, with 7 to 10% channeled to growth. A generalized pattern of utilization of dietary energy based upon collective investigations with *Haliotis* sp. is presented and suggests that 40–50% is generally lost to fecal production and approximately 50% of assimilated energy is lost to respiration.

THE RELATIONSHIP BETWEEN PRODUCT QUALITY AND BIOCHEMICAL COMPOSITION IN SEA URCHIN GONADS, WITH EMPHASIS ON TASTE AND TEXTURE. Trine Dale, Sten I Siikavuopio, Anders Aksnes, Britt Hoppe and Mats Carlehög, Norwegian Institute of Fisheries and Aquaculture Research, Fiskerikorskning, 9291 Tormsø, Norway.

Whilst most sea urchin feeds at this point seems capable of promoting gonad growth, there is scope for improvement with respect to texture and taste. This study aims to identify possible common biochemical compounds associated with good (sweet, firm) and bad (bitter, melting) quality in sea urchins, and furthermore how compounds correlated with good quality is influenced by diet. The study is combining sensory analysis with analysis of proximate composition and free amino acids. In part one of the study, three species of wild sea urchins are compared: *Strongylocentrotus droebachiensis* (from Norway and Canada), *S. intermedius* and *Echinus esculentus*. In part two *S. droebachiensis* were fed five diets of different protein and carbohydrate content. In the wild sea urchins there was no apparent relationship between texture and proximate composition. There appear to be a relationship between the intensity of bitter taste and the content of valine and/or the content of alanine and glycine (increased bitterness with increased content of valine and/or reduced content of alanine and glycine). The intensity of sweet taste appears to be related to content of alanine and glycine. The sensory panel identified significant differences in quality between gonads from sea urchins fed different diets. The data from the biochemical analyses of these gonads are not yet analysed.

GEODUCK AQUACULTURE IN NORTH AMERICA.**Jonathan P. Davis**, Taylor Resources, Inc. Quilcene, WA 98386.

Aquaculture development for geoduck clams (*Panopea abrupta*) increased rapidly over the last decade on the US and Canadian west coast. Intertidal and sub-tidal culture was initiated in the late 1980s by the Washington Department of Fisheries in an enhancement program to replace clams removed via commercial harvest. Though unsuccessful as an enhancement tool, rearing methods enabled aquaculture development to occur rapidly in Washington State and BC. Culture activities were initiated in the mid 1990s in both Washington State and BC, and more recently in Alaska and Oregon and expanded rapidly as more reliable methods for intertidal and sub-tidal grow out of geoducks were developed. Intertidal culture has been the focus in Washington where tidelands are either owned or leased, while sub-tidal plantings have been required in BC due mainly over restrictions to utilization of tidelands. Limitations on the growth of the industry are based mainly on seed availability and access to suitable intertidal sites. Though 4–6 years are necessary to produce a harvestable product, in excess of 200,000 KG are harvested annually with a landed value of US \$4.5 million currently with significant expansion in supply expected over the next decade. Developments in hatchery rearing of larvae and seed include a better understanding of nutritional requirements, the provision of live algal feeds high in polyunsaturated fatty acids, and husbandry practices that focus on controlling clam density and pathogenic bacteria.

DIGESTIVE ENZYME ACTIVITY IN BIVALVE TISSUES.**Lewis E. Deaton**, University of Louisiana at Lafayette, Lafayette, LA 70504.

While the major organ of digestion in bivalve molluscs is the digestive gland, there is direct and indirect evidence that the gills secrete some digestive enzymes. These enzymes may play a role in internal defense, but they may also be secreted to 'pre-digest' material that is to be swallowed by the animal. This latter notion is consistent with recent research demonstrating that at least in some species of bivalve, the sorting of material trapped on the gills into food to be swallowed and material to be rejected occurs on the gill itself. We have used API ZYM test kits (bioMérieux) to compare the activity of 19 assorted digestive enzymes in the gill, digestive gland, and adductor muscle of the quahog *Mercentaria mercenaria* and the oyster *Crassostrea virginica*. For most of the enzymes, the activity was highest in the digestive gland and lowest in the adductor muscle. Activities in the gill were intermediate between the former two tissues. Assays are being developed to examine the activity of laminarinase, cellulase, amylase, and proteases in gill, digestive gland and adductor muscle in *M. mercenaria* and *C. virginica*.

SURVIVAL AND GROWTH OF *CRASSOSTREA VIRGINICA* LINES IN CHESAPEAKE AND DELAWARE BAYS.**Lionel Dégremont¹, Standish K. Allen Jr.¹, E. M. Bureson¹ and Gregory Debrosse²**, ¹Virginia Institute of Marine Science, Aquaculture Genetics and Breeding Technology Center, 1208 Greate Rd., Gloucester Point, VA 23062, ²Haskin Shellfish Research Laboratory.

As a part of our oyster breeding program developed to enhance resistance against MSX and Dermo in *Crassostrea virginica*, eight lines and one control were produced in 2004 and deployed at four sites in Virginia (Burton's Bay, York River, Kinsale and Lynnhaven) and one site in the Delaware Bay (Cape Shore). First results, excluding the Cape Shore site, showed difference of mortality among sites in November 2005 with the highest mortality at Burton's Bay (57%), intermediate at the York River and Lynnhaven sites (40–46%) while oysters at Kinsale showed the lowest mortality (10%). The mortality mostly occurred between August and November except at Burton's Bay where it happened in April. Significant differences of mortality were also observed among lines in each site and a significant line by environment interaction was found which is easily explainable by the absence of significant mortality at Kinsale and the unusual mortality event occurring in April at the Burton's Bay. For growth, oysters deployed at York River and Lynnhaven showed the slowest growth while those at Kinsale and Burton's Bay showed the fastest. Finally, our results suggested which line would be most useful according to their yields across environments. For example in Burton's Bay, CROS-Breed line yielded 2.5 as much as the control while at Kinsale, a Louisiana strain would be preferred, yielding 60% greater than the control. Pathology analyses indicate MSX explains the mortalities observed during the summer and results from the fall sampling will provide more perspective on the cause of the mortalities.

THE OTHER SIDE OF RESTORATION. **Donatella Del Piero**, Viagrogrieri 10, Dipartimento di Biologia, Università Di Trieste, 34133 Trieste, Italy.

The tentative restoration done by the fishermen of shellfish beds (mainly *Chamelea gallina*) in Northern Adriatic seems to be far from optimization. Traces of uncontrolled restocking operations date back at least to 1990, but it doesn't seem to be decisive for stock enhancement. We have, instead, evidence of overall heavy depletion in stock and low growth rates, so the trade organisation are asking for diminishing the minimum legal size, actually set to 25 mm, till 20 mm, due to lack of legally marketable clams. This is a very old problem in the area and is of course questionable if the lack of response (e.g. to fleet reduction and long closure season) may reflect changes in the whole system or is an effect of gear improvement, bad knowledge of population dynamic, physiology etc. that must be known for implementing restoration programs.

LAND-BASED SEA URCHIN CULTURE SYSTEM. Michael Devin, University of Maine.

We are conducting a project to further develop and refine the culture conditions to optimize the growth of juvenile green sea urchins (*Strongylocentrotus droebachiensis*), a commercial species not previously cultured as juveniles. As part of this project we are investigating the effects of diet on growth from the early- to late-juvenile stages. To study growth we conducted an experiment whereby juvenile sea urchins were divided into seven treatments (*Ulva*, *Laminaria*, *Palmaria*, a mixed diet containing all three macroalgae, *Laminaria* augmented with mussel, *Palmaria* augmented with mussel and an artificial palletized formulation (Dr. Addison Lawrence formulation). Urchins were placed in colanders that contain a buoyant material so that they float with the rim approximately two cm above the surface. There were four replicates for each treatment. The animals were fed *ad libitum* twice weekly. Growth was highest in the mixed diet (mean wt. 26.0 gm), followed by the treatments of *Palmaria* (mean wt. 23.6 gm) and the artificial formulation (mean wt. 23.6 gm). Higher growth rates found in treatments containing *Palmaria* are postulated to be due to the high percentage of protein and calcium found in *Palmaria* compared with *Ulva* and *Laminaria*. Although, juvenile sea urchins appear to grow fastest when fed *Palmaria* relative to *Ulva* and *Laminaria*, the mixed treatment produced the largest animals.

THE EFFECTS OF DIET ON GROWTH OF THE GREEN SEA URCHIN (*STRONGYLOCENTROTUS DROEBACHIENSIS*) FROM THE EARLY- TO LATE-JUVENILE STAGES. Michael G. Devin, Henry D. Stence, and Robert J. Peacock. R. J. Peacock Canning Company, 72 Water Street, Lubec, Maine 04652.

We are conducting a project to further develop and refine the culture conditions to optimize the growth of juvenile green sea urchins (*Strongylocentrotus droebachiensis*), a commercial species not previously cultured as juveniles. As part of this project we are investigating the effects of diet on growth from the early- to late-juvenile stages. To study growth we conducted an experiment whereby juvenile sea urchins were divided into seven treatments (*Ulva*, *Laminaria*, *Palmaria*, a mixed diet containing all three macroalgae, *Laminaria* augmented with mussel, *Palmaria* augmented with mussel and an artificial palletized formulation (Dr. Addison Lawrence formulation). Urchins were placed in colanders that contain a buoyant material so that they float with the rim approximately two cm above the surface. There were four replicates for each treatment. The animals were fed *ad libitum* twice weekly. Growth was highest in the mixed diet (mean wt. 26.0 gm), followed by the treatments of *Palmaria* (mean wt. 23.6 gm) and the artificial formulation (mean wt. 23.6 gm). Higher growth rates found in treatments containing *Palmaria* are postulated to be due to the high percentage of protein and calcium found in *Palmaria* compared with *Ulva* and *Laminaria*. Although, juvenile sea ur-

chins appear to grow fastest when fed *Palmaria* relative to *Ulva* and *Laminaria*, the mixed treatment produced the largest animals.

SHELLFISH CROP AND CULTURE GEAR FOULING IN THE PACIFIC NORTHWEST. Bill Dewey, Taylor Shellfish Company, 130 SE Lynch Rd., Shelton, WA 98584.

Shellfish culture in the United States Pacific Northwest like many areas of the world is complicated by biofouling of shellfish crops and aquaculture gear. Growers in this part of the country are plagued by such things as barnacles, overcatch of oysters on single oyster crops, suffocating macroalgae as well as *Spartina* and eelgrass infiltration. Subtidally, crops and gear are fouled by barnacles, bryozoans, sponges and tunicates. Recently the discovery of non-native colonial tunicates (*Didemnum* sp.) in Puget Sound has subtidal shellfish growers concerned. Depending on circumstances and severity biofouling can have detrimental effects on growth and survival of crops. Each geographic farm location typically has its own unique fouling issues. Fouling will vary geographically, annually and seasonally. In the case of intertidal culture, which is the primary means of culturing in the Pacific Northwest, fouling will also vary with tidal elevation. Assorted husbandry or culture strategies are employed to minimize and/or avoid fouling or to clean fouling organisms off gear and crops.

RESTORING *MERCENARIA* ON LONG ISLAND: CONDITION AND SPAWNING OF TRANSPLANTED HARD CLAMS IN SANCTUARIES IN LONG ISLAND, NEW YORK. Michael H. Doall¹, Dianna K. Padilla¹, Carl Lobue² and Laurie Perino¹. ¹Stony Brook University, Department of Ecology and Evolution, Stony Brook, NY 11794-5245. ²The Nature Conservancy.

On Long Island, New York, the Nature Conservancy has spearheaded efforts to restore *Mercenaria mercenaria* populations by creating sanctuaries of high densities of spawning clams to reduce sperm limitation for fertilization and thereby increase the potential for recruitment. Success requires that the clams survive, obtain enough energy for gonad development, and spawn. To assess the condition of transplanted clams in sanctuaries established in the Great South Bay and Peconic estuaries, we monitored condition index (CI), computed as the ratio of the dry mass of soft tissue to the internal shell cavity capacity, and qualitative rankings of gonad ripeness during 2004 and 2005. Changes in CI were correlated with changes in gonad ripeness in all sanctuaries monitored; CI increased as gonads ripened and decreased as gonad tissue and gamete concentrations diminished. Decreases in CI and gonad ripeness coincided with the appearance of hard clam larvae in the plankton, indicating that spawning had occurred. The magnitude and timing of changes in CI and gonad ripeness varied between populations of clams in different sanctuary sites, and between years for the same populations. Temperature appeared to be one

exogenous factor influencing the timing of reproductive cycles, but spatial-temporal variability in other environmental parameters, such as food quantity and quality, may also explain differences between populations and between years. The prior history of transplanted clams, especially their source location, also appeared to influence condition and timing of gonad development during the first year after transplant.

GEODUCK FARMING 101—THE TRIALS AND TRIBULATIONS OF STARTING A NEW FARM. Peter Downey, Discovery Bay Shellfish Inc.

This presentation will examine issues encountered while planting three acres of geoduck during the 2005 planting season. Issues to be reviewed include securing appropriate tidelands, coming to terms with regulatory agencies and tribes, developing a labor pool, ensuring seed survival, planting logistics and dealing with inclement weather and wind driven waves.

HUSBANDRY PRACTICES AND ASSOCIATIONS WITH PRODUCTIVITY IN PRINCE EDWARD ISLAND MUSSEL FARMS. Andre Drapeau¹, Luc Comeau² and Jeff Davidson¹. ¹University of Prince Edward Island, ²Department of Fisheries and Oceans.

Associations between husbandry practices and blue mussel (*Mytilus edulis*) productivity in Prince Edward Island (PEI), Canada farms were investigated. Husbandry was measured using SCUBA in Tracadie Bay (2002–2004) and in 16 embayments in 2003. Measurements related to 1-year-old crop exposed to approximately eight months of husbandry practices. Between 2002 and 2004, longline spacing, sock spacing and sock weight in Tracadie Bay ranged from 5 to 24.85 m, 27.50 to 40.40 cm and 2.86 to 15.49 kg respectively, while across PEI husbandry ranged from 1.50 to 29.54 m, 26.38 to 62.40 cm and 1.48 to 16.87 kg respectively. Sock spacing significantly increased by 32% (+12 cm) over the years and was directly responsible for significantly decreasing lease stocking density by 25% (–6 socks/100 m²). Regression models revealed that sock spacing was positively associated with mussel sock weight in Tracadie Bay (2002) and across PEI (2003). In Tracadie Bay, sock spacing was related to sock weight in 2002 and mussel condition in 2004. Each additional 10 cm between socks resulted in raising predicted sock weight by 1.15 kg and mussel condition index by 1.60, while across PEI, sock weight increased 0.74 kg. This gain is plausible and likely driven by reduction in intraspecific competition between mussels for available food resources. However, the observed correlation was statistically significant only for a single year in Tracadie Bay (2002), while marginally significant across PEI (2003). This suggests that the effect of sock spacing was dynamic and dependent upon food availability within the water column.

OYSTER SURVIVAL AND GROWTH IN THE BARATARIA ESTUARY. Ronnie Duke and Earl J. Melancon, Department of Biological Sciences, Nicholls State University, P.O. 1, Thibodaux, LA 70310.

We documented oyster responses to natural environmental events in the historically productive zone of the Barataria estuary, part of the Davis Pond Mississippi River Diversion outfall area. The diversion has operated minimally with no measurable impact on oysters. During the study there were two naturally occurring reduced-salinity events (<5 ppt), two tropical storms and three hurricanes.

Oyster populations were studied monthly from April 2004 to November 2005 for survival, size frequency and condition index. In June/July 2004 salinities were well below 5ppt across most of the estuary and all oysters died except at the most down-estuary site. Oysters rebounded with a good estuary-wide spat set in September/October 2004. All fall 2004 set oysters survived an estuary-wide winter 2005 reduced-salinity event. Oysters exhibited highest condition indices during winter and lowest during summer.

Seed-sized oysters, 44 mm in shell length, were tagged in fall 2004 at two sites for monthly growth comparisons. From September 2004 to August 2005 oysters grew to 64.3 ± 6.9 mm at the up-estuary site and to 77.5 ± 7.3 mm at the down-estuary site. A shell length of 65 mm is minimum sack size acceptable for oysters harvested from private leases. Preliminary comparisons of the fall 2004 sets at 10 sites for size frequency exhibited a similar pattern of faster growth down-estuary.

This information becomes important for natural resource managers and oystermen as adaptive management strategies are developed so that both diversions and oysters can co-exist. Oystermen must decide if they want to harvest seed-size oysters or wait the additional time to harvest sack-sized oysters.

OYSTER AQUACULTURE IN A PACIFIC NORTHWEST (USA) ESTUARY: A PLEA FOR TAKING A LANDSCAPE-ECOSYSTEM PERSPECTIVE. Brett R. Dumbauld¹, Jennifer Ruesink², and Miranda Wecker³. ¹U.S. Department of Agriculture, Agricultural Research Service, 2030 SE Marine Science Dr., Newport, OR 97365, ²University of Washington, Department of Biology, WA 98195, ³University of Washington, Olympic Natural Resources Center, Forks, WA 98331.

Commercial shellfish harvest in Willapa Bay, Washington has been an important source of oysters for 150 years and aquaculture in this estuary alone produces about 10% of the U.S. oyster harvest. Management policies for estuarine tidelands in the Pacific Northwest are based on general descriptors and perceptions from research conducted elsewhere (e.g. submerged aquatic vegetation provides structure which increases abundance and diversity of other organisms), resulting in regulations such as no-net loss of aquatic vegetation which are applied on a very small individual permit scale. While results of recent studies conducted at this scale

in Willapa Bay and other Pacific coast estuaries do in-part confirm the generality of these descriptors, these estuaries appear to function slightly differently and the role of cultured oysters as habitat and as secondary consumers in these systems is newly described. Scale is clearly an issue and recent mapping efforts in Willapa Bay suggest that managers should view aquaculture from an estuarine landscape perspective. Techniques that have recently been applied for analyzing the role of terrestrial agriculture in otherwise forested or grassland ecosystems suggest that movement corridors and edge-interior ratios are important considerations. Preliminary results from such an exercise conducted in Willapa Bay suggest that traditional policies which seek to conserve other large invertebrate or vertebrate fisheries by protecting one habitat (aquatic vegetation) may need to be reconsidered once results are confirmed by directed studies conducted at this landscape scale. Considering local differences, best management practices could then also be regulated and implemented at this scale.

PERKINSUS OLSENI IN VITRO ISOLATES FROM NEW ZEALAND CLAMS (*AUSTROVENUS STUTCHBURYI*).

Christopher F. Dungan¹, Rosalee M. Hamilton¹, Kimberly S. Reece², Jessica A. Moss², and Ben K. Diggles³. ¹Maryland Dept. of Natural Resources, Oxford Laboratory, ²Virginia Institute of Marine Science, ³DigsFish Services Pty Ltd, Queensland, Australia.

Prevalent *Perkinsus* sp. infections have been reported in *Austrovenus stutchburyi* venerid clams (cockles) from northern New Zealand, since 2000. Sequencing of rRNA gene complex ITS- and NTS-regions of genus-*Perkinsus* PCR amplicons from infected *A. stutchburyi* DNA templates, have consistently indicated the presence of *P. olseni* parasites. However, *in vitro* *Perkinsus* sp. isolates have been unavailable to date for comprehensive morphological and genetic evaluation of the New Zealand parasite's identity. We report *in vitro* isolation, propagation, cloning, and cryopreservation of four *Perkinsus* sp. isolates from a 2005 sample of *A. stutchburyi* cockles from northern New Zealand's Mangamangaroa Stream (24°C, 32 ppt). Isolates were propagated *in vitro* despite a moderate prevalence (24%) of low-intensity *Perkinsus* sp. infections in the sampled cockles. These isolates showed morphometric similarities and differences with characteristics reported for *P. olseni* isolates from other hosts and locations. Although their frequency of continuous *in vitro* zoosporulation was low, one typical isolate was induced to wholesale (>70%) zoosporulation by a transient, 48-h passage through ARFTM. Nucleotide sequences of rDNA ITS-regions from our isolates consistently grouped them with *P. olseni* sequences in phylogenetic analyses, suggesting that *Perkinsus* sp. infecting New Zealand *A. stutchburyi* clams are conspecifics of destructive and broadly distributed *P. olseni* parasites of several eastern Asia clams, diverse Australian clams and abalone, and several European clams.

WASHINGTON STATE GEODUCK AQUACULTURE PROGRAM. Sarah Dzinbal, Celia Barton and Jeffrey Schreck. Washington State Department of Natural Resources, Aquatic Resources, P.O. Box 47027, Olympia, WA 98504-7027.

The 2003 Washington State Legislature directed the Washington State Department of Natural Resources (DNR) to determine the feasibility of geoduck aquaculture on state owned aquatic lands (SOAL). Between July 2003 and June 2005, DNR contracted with the University of Washington and other entities to compile reports that would allow that determination to be made. DNR testified to the 2005 Legislature that geoduck aquaculture on SOAL is feasible, but recommended that the project proceed with caution by authorizing the use on twenty to twenty-five acres of SOAL per year. DNR submitted a budget request for additional funds to implement a leasing program for geoduck aquaculture on SOAL, but unfortunately did not receive those funds. DNR believes that aquaculture is an important use and, as such, has moved forward with implementation of a geoduck aquaculture-leasing program. The lack of dedicated funding has necessitated a different approach—DNR is designing a monitoring program that will require some of its geoduck aquaculture lessees conduct scientific monitoring on their leaseholds throughout the first geoduck growing cycle. The results of this monitoring will allow DNR to fully assess the environmental effects of geoduck aquaculture, and further allow a determination on the long-term feasibility of this use. Twenty to twenty-five acres of SOAL will be put up for competitive bid in the summer of 2006. Potential lessees will respond to the Request for Proposals by providing a summary of their proposed activities, including the scientific monitoring aspect.

WASHINGTON STATE GEODUCK FISHERY MANAGEMENT. Sarah Dzinbal, Celia Barton and Todd Palzer. Washington State Department of Natural Resources, Aquatic Resources, P.O. Box 47027, Olympia, WA 98504-7027.

The Washington State Department of Natural Resources (DNR), as the steward of publicly owned lands, manages approximately 2.4 million acres of aquatic lands in Washington. One of its roles is to co-manage the wild stock geoduck fishery, and the agency does this together with the Washington Department of Fish and Wildlife (WDFW) and the Treaty Tribes in western Washington. The geoduck fishery has been open since 1970 and is managed to be sustainable for future generations of citizens in Washington State. The state and tribes work collaboratively to quantify geoduck biomass by conducting tract surveys on a rotational basis. WDFW sets the Total Allowable Catch for each fishery year—2.7% of the total commercial geoduck biomass—and the state and tribes share this resource equally. DNR publicly auctions the right to harvest the state's share of the geoduck resource, in the form of geoduck quotas. This generates approximately \$8 million per year for the state, which is used by a number of state and local government entities for aquatic land enhancement and management

work. The successful bidders at auction sign harvest agreements with DNR; the agreements allow companies to harvest specified pounds of geoducks from specified tracts of state owned aquatic lands for a specified period of time. The agreements are enforced by DNR's commercial dive team, which conducts daily fishery compliance operations on the geoduck tract every day the state fishery is open. The fishery is a year-round dive fishery.

USE OF THE OLIGOHALINE CLAM *RANGIA CUNEATA* AS A BIVALVE INDICATOR OF WATERSHED ALTERATIONS IN SOUTHWEST FLORIDA. Vincent Encomio¹, Christina Panko¹, Ernest Estevez² and Aswani K. Volety¹.

¹Coastal Watershed Institute—Florida Gulf Coast University, 10501 FGCU Blvd S., Fort Myers, FL 33965, ²Center for Coastal Ecology—Mote Marine Laboratory Sarasota, Sarasota, FL.

In Florida, freshwater releases from Lake Okeechobee result in dramatically lowered salinity, adversely affecting bivalve populations downstream in the Caloosahatchee River. Additionally, high sediment loading due to increased freshwater flow or dredging may adversely affect bivalve condition. The impact of watershed alterations on oysters is part of ongoing research in SW Florida. The use of oysters as a sentinel organism, however, only covers the mesohaline (10–30 parts per thousand (ppt)) regions of the estuary. Few, if any studies have examined effects on bivalves in the oligohaline (<10 ppt) portions of the Caloosahatchee estuary. The clam *Rangia cuneata* is found extensively in oligohaline regions of the Caloosahatchee and may be a useful bivalve indicator of sedimentation and altered salinity. Clams were exposed for thirty days to clay (<4 µM grain size) and silt (40–60 µM) at 0, 1 and 2 grams/clam/day. At 0, 10, 20 and 30 days condition index (dry tissue weight: dry shell weight), glycogen, lipid and protein content in clams were measured. Condition index decreased significantly over time ($p = 0.0177$) but not with sediment type and dose. Despite wide physiological salinity tolerances, *R. cuneata* cannot maintain stable populations beyond 1–15 ppt (Hopkins et al, 1973), making it vulnerable to extended freshets and droughts. Distributions of live and dead shells indicate higher proportions of dead shells near the head of the estuary, possibly indicative of past freshets. Salinity tolerances and responses to interactive stress (e.g. temperature) will be examined in the lab to corroborate patterns seen in the wild.

COMMUNITY SHIFT ASSOCIATED WITH SHELLFISH AQUACULTURE IN TWO MID-ATLANTIC ESTUARIES.

Patrick Erbland and Gulnihal Ozbay, Delaware State University.

Populations of the eastern oyster (*Crassostrea virginica*) and its associated fishery have been declining in the State of Delaware and greater Mid-Atlantic region of the United States for decades.

This shortage of oysters continues despite intensive husbandry of oyster reefs by fishers and government agencies. Consequently there is interest in the culture of *C. virginica* enclosed in "grow out gear" (GOG) to increase yields. Such a practice has a multitude of associated impacts on the host ecosystems. These include reduced nutrient load in the water column (Ulanowicz and Tuttle 1992) and enrichment of benthic sediments (Nugues et al 1996). The enhanced levels of sport fish such as Striped Bass (*Morone saxatilis*) and Bluefish (*Pomatomus saltatrix*) found on oyster reefs (Harding and Mann 1998) may also exist on oyster farms. This is a two part study investigating shifts in the benthic and infaunal communities. We will compare the diversity and abundance of species inhabiting subtidal "Rack and Bag" type GOG, containing *C. virginica*, with an adjacent, created *C. virginica* reef in Indian River Bay, DE. Secondly, we will compare the diversity and abundance of infaunal species present below intertidal oyster gear with an adjacent control area of open sand flat on the eastern shore of Delaware Bay. This study will provide insight into the ecological impact of shellfish aquaculture and be useful in incorporation of *C. virginica* aquaculture into the management schemes of concerned regulatory agencies.

ADDITIONAL EVIDENCE OF HIGH RESISTANCE TO *HAPLOSPORIDIUM NELSONI* (MSX) IN THE NATIVE OYSTER POPULATION OF DELAWARE BAY. Susan Ford and David Bushek. Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Avenue, Port Norris, NJ 08348 USA.

Natural selection during the first *Haplosporidium nelsoni*-caused epizootic in Delaware Bay oysters resulted in the development of a degree of resistance to mortality caused by the pathogen throughout the Bay. Until the late 1980s, this level of resistance did not change because most of the surviving oysters were protected from additional selection as they resided in the low salinity region of the Bay. The development of a second level of resistance was signaled after heavy *H. nelsoni*-caused mortalities in the mid 1980s occurred during a severe drought and prevalence of the pathogen subsequently declined markedly. Susceptible controls exposed beside natural set in the lower bay continued to become heavily infected, whereas the natural set had prevalences of 0 to 10%. To determine whether oysters on the low-salinity beds were similarly resistant, we exposed oysters from two upper-bay beds along with lower bay natives and susceptible controls in Cape May Harbor where *H. nelsoni* pressure has been heavy. Six months later, prevalence of susceptible oysters was 90%, with most infections being advanced. At the same time, prevalence in the two upper bay groups was only 5 to 20% with mostly light, localized infections. This confirms that a high degree of resistance is now present throughout the Bay. In contrast, there is little evidence that

significant resistance to infection by *Perkinsus marinus* has developed despite continuous exposure and consequent mortality over the past 15 years.

COMPARATIVE EFFECTS OF NEUROTRANSMITTERS AND CALCIUM BLOCKERS ON ISOLATED GILLS AND WHOLE ANIMALS OF THE MUSSEL, *MYTILUS EDULIS*.

Dana M. Frank, J. Evan Ward, Sandra E. Shumway¹ and Lewis Deaton². ¹University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340, ²University of Louisiana at Lafayette.

It is generally accepted that the lateral cilia of bivalve molluscs are inhibited by dopaminergic systems and excited by serotonergic systems. Most of this experimentation has been carried out on excised gills of the mussel, *Mytilus edulis* and not on whole animals. We conducted preliminary tests to compare the effects of the neurotransmitters serotonin (5 HT), dopamine (DA), and apomorphine and the calcium channel blocker lanthanum on pumping activity of intact *M. edulis* and the ciliary activity of isolated gill tissue. We also exposed isolated gill filaments to the calcium channel blockers cobalt chloride and verapamil. Whole animals and freshly excised gill sections were kept in filtered seawater at ambient temperature (~20°C). Experimental drug was added directly to the bath water. Activity of the lateral cilia of isolated gills was monitored with an inverted compound microscope. Water processing rates of whole animals were examined using particle image velocimetry (PIV). Lanthanum induced shedding of the gill epithelia in excised sections and in whole animals obviating any effect on the lateral cilia. Cobalt chloride, DA, and verapamil had no effect on gill sections. When exposed to 1×10^{-6} M apomorphine, 30% of gill sections showed some inhibition; 50% were inhibited at 1×10^{-5} M. In the whole animal, 1×10^{-6} M apomorphine had a significant negative effect on velocities of particles in the excurrent flow. 5 HT appeared to increase synchrony (metachronism) of the lateral ciliary beat in isolated gill sections. Preliminary work suggests that neural agents affect whole animals differently than isolated gill tissue.

OPTIMIZATION OF OXYTETRACYCLINE TREATMENT IN TWO ABALONE SPECIES, *HALIOTIS SORENSENI* AND *H. RUFESCENS*.

Carolyn S. Friedman¹, B. B. Scott¹, R. E. Strenge¹, N. A. Wight¹, Thomas B. McCormick² and George Trevelyan³. ¹School of Aquatic and Fisheries Sciences, University Washington, Box 355020, Seattle, WA 98195, ²Channel Islands Marine Research Institute, Port Hueneme, CA, ³The Abalone Farm, Inc., Cayucos, CA.

Withering syndrome (WS), a rickettsial disease, causes losses of wild and farmed abalone. The endangered white abalone, *Haliotis sorenseni*, is highly susceptible to WS and information on management of this disease is essential for successful restoration. White abalone were fed a medicated diet containing oxytetracy-

cline (OTC) for 20 d; digestive gland (DG) and foot muscle (FM) were assayed for OTC and rickettsia at days 3, 18, 24, 40, 67, 80, 110, 129, 165 and 185 post-medication. Abalone were rechallenged with rickettsia at 24, 40, 67, 146 and 171 d. DG contained higher levels and retained OTC longer than FM. Mean DG drug levels peaked at 996 ppm at 25 d post-medication and leveled off at 30 ppm after 68 d. FM peaked at 18 ppm and declined to below 2 ppm, the FDA tolerance level, between 25 and 41 d. Protection from rickettsial infections occurred in abalone with over 50 ppm in the DG. We investigated the pharmacokinetics of one oral OTC dose in red abalone and that of 1, 2 or 3 intramuscular (IM) injections with Liqueamycin-LA 200 in white abalone. One oral dose cleared 90–100% ($p < 0.05$) of infections. A mean of 239 ppm OTC was detected in the DG 5 d after medication followed by depletion to 2.34 ppm after 130 d. In a second trial, 688 ppm accumulated in the DG at 1 d and declined to 326 ppm by day 5. Interestingly, total body OTC was only 89 ppm at day 1 (688 ppm in DG). IM injections resulted in DG accumulations of 7.15, 20.3 and 27.4 ppm after 1, 2 and 3 doses, respectively.

DEVELOPMENT AND APPLICATION OF TYPE I MARKERS FOR LINKAGE MAPPING AND POPULATION GENETICS IN *CRASSOSTREA* SPECIES.

Patrick Gaffney¹, Hyungtaek Jung¹, Woo-jin Kim², Robin Varney¹ and Coren Milbury¹. ¹University of Delaware, College of Marine Studies, 700 Pilottown Rd., Lewes, DE 19958, ²National Fisheries Research & Development Institute.

In oysters, nuclear markers developed for linkage mapping and the analysis of population structure include allozymes, anonymous single copy DNA (scnDNA) loci, microsatellites, and most recently, single nucleotide polymorphisms (SNPs). The emergence of substantial expressed sequence tag (EST) databases for *Crassostrea virginica* and *C. gigas* has enabled researchers to probe candidate genes for polymorphisms by direct DNA sequencing. Because the number and locations of introns in genes selected from EST databases are unknown, primer design for amplification from genomic DNA can be challenging. Taking advantage of the reduced frequency of introns in the 3'UTR of invertebrate genes, we have designed primers for small (~300 bp) amplicons spanning the 3' end of coding sequence and the 3'UTR. These primers typically provide successful amplifications and often amplify putatively homologous sites in closely related *Crassostrea* species. High levels of polymorphism ensure that even short amplicons usually have one or more SNPs suitable for genotyping. Applications of markers developed to date will be discussed, including linkage mapping in *C. virginica* and *C. gigas*, population genetics and taxonomy of Atlantic and Asian oysters, and monitoring restoration efforts involving hatchery-produced seed.

REPRODUCTIVE TIMING AND SUCCESS OF FRESHWATER MUSSELS. Heather S. Galbraith, Caryn C. Vaughn and Daniel E. Spooner. Oklahoma Biological Survey and the University of Oklahoma.

Freshwater mussels are among the most imperiled groups of aquatic organisms on earth. Their diversity, dominance in benthic biomass, and unique life histories make them important contributors to stream ecosystem function while at the same time have made them susceptible to anthropogenic interferences such as river regulation, impoundments, and global warming. High species richness and large numbers of closely related species within mussel beds has proven paradoxical to typical views of speciation in broadcast spawning organisms. The goal of our research is to determine the reproductive timing, success, and isolation of three closely related species of freshwater mussels by addressing the following questions: 1) What are the mechanisms of reproductive isolation in freshwater mussels? 2) How is reproductive timing regulated and important to fertilization success in freshwater mussels? In order to conserve mussel communities, understanding the processes of speciation and reproduction are vital. This work will be some of the first to provide an evolutionary and ecological perspective on one of the most critical and little understood periods of the freshwater mussel life cycle, specifically that prior to fertilization.

GREEN CRABS (*CARCINUS MAENAS*) AS THE GRIM REAPER: DESTRUCTION OF EELGRASS BEDS IN NOVA SCOTIA. David J. Garbary and A. G. Miller. Department of Biology, St. Francis Xavier University, Antigonish, Nova Scotia, Canada B2G 2W5.

Following the first appearance of invasive *Carcinus maenas* in the southern Gulf of St. Lawrence in the early 1990s, 385,000 crabs km⁻² occurred in Antigonish Harbour in 2000. Eelgrass (*Zostera marina*) which had large stable populations in the estuary for the previous 60 years declined by 95% in 2001, and many parts of the harbour were devoid of living eelgrass. This decline also occurred in adjoining estuaries where large numbers of crabs also occurred, but did not take place in estuaries further west and north where green crabs had not yet invaded, or numbers were low. In July-August 2002, shoot density of eelgrass at an experimental site in Tracadie Harbour with high crab numbers declined by 75% when a control harbour with few crabs showed increasing shoot density. A field experiment using 1.5 m² cages, with and without green crabs, suggested that *C. maenas* was responsible for the loss of eelgrass. Telephone interviews with knowledgeable observers around Nova Scotia also suggested a correlation between declining eelgrass populations and increasing numbers of crabs during the previous ten years. The impact of green crabs on eelgrass is associated with their foraging activity in which they produce pits up to

30 cm wide and 15 cm deep. During foraging, eelgrass shoots are dislodged by crab digging, or the shoot bases are shredded, causing release of whole shoots into the drift. Since 2001, green crab numbers have been in decline in Antigonish Harbour, and there has been a substantial recovery of *Z. marina*.

SYNTHESIS OF 15 YEARS RECORDS FOR *HAPLOSPORIDIUM NELSONI* IN *CRASSOSTREA GIGAS* IN FRANCE. Céline Garcia, Isabelle Arzul, Bruno Chollet, Sylvie Ferrand, Cyrille François, Jean-Pierre Joly, Laurence Miossec and Maeva Robert

Haplosporidian parasites have been described in several bivalves such as oysters. The species *Haplosporidium nelsoni* is particularly well known in the American oyster *Crassostrea virginica* in which it induces massive mortalities. *H. nelsoni* was also detected in Pacific oyster *C. gigas* from different parts of the world. In France, it was detected for the first time in 1993 but other haplosporidian parasites had already been observed before in *C. gigas*.

The data analysis of the French network for surveillance of mollusk health between 1990 and 2004 showed a very sporadic detection of *H. nelsoni* (histology and confirmation by *in situ* hybridization); its detection frequency is of 1‰ per year on average and can reach 1% in a given area. It was mainly detected in oyster spat and in summer period (from May to August). It was essentially present along French Atlantic coasts, particularly in estuaries or in sheltered bays. In 2005, its detection frequency increased (1‰ to 1%) and reached 7 to 10% in some areas. As previously recorded, the parasite was observed in connective tissue from different organs and also in the epithelia of digestive diverticulae where spores were observed. It is the first time that a sporulation of *H. nelsoni* in *C. gigas* is described in France. This observation and the increase of its detection can raise some questions: does the parasite behaviour in Pacific oyster change? Does it adapt to the French environmental conditions? Does it present a risk for the French oyster culture?

DETECTION AND DISTRIBUTION OF QUAHOG PARASITE UNKNOWN IN THE COASTAL MARINE ENVIRONMENT. R. J. Gast¹, D. M. Moran¹, K. R. Uhlinger², D. R. Leavitt³ and R. Smolowitz². ¹Woods Hole Oceanographic Institution, Woods Hole, MA 02543, ²Marine Biological Laboratory, Woods Hole, MA, ³Roger Williams University.

Quahog Parasite Unknown (QPX) is a significant cause of hard clam mortality along the Northeast coast of the United States. The QPX organism is classified as a thraustochytrid protist, and members of this protistan family are generally saprophytic and com-

monly found in the marine environment. No viable method was available to reliably survey the natural environment for QPX, to rapidly assess the persistence of the organism in previously affected plots, and to screen large numbers of clams potentially exposed to the disease. Here we report on a PCR-based method that we have developed that permits sensitive detection of QPX in natural samples and seed clams. With our method, between 10–100 QPX cells can be detected in 1 L of water, 1 gram of sediment and 100 mg of clam tissue. We have used the method to examine one hundred 15 mm seed clams, and found that 10–12% of the clams were positive for the presence of the QPX organism, although only 1% showed histological evidence of infection. The method has also been used in a survey for the presence of the pathogen in environmental samples from a site experiencing severe infection and a site with low to no infection. This survey has revealed the presence and year-round persistence of QPX in the environment, even in the absence of large-scale die-off.

CONDITION OF FRESHWATER MUSSELS HELD IN REFUGIA AT THE WHITE SULPHUR SPRINGS NATIONAL FISH HATCHERY, WEST VIRGINIA. Catherine M. Gatenby¹, Matthew A. Patterson¹, Julie L. Devers¹ and Danielle A. Kreeger². ¹United States Fish and Wildlife Service, ²Delaware River Basin Commission.

The USFWS established a refugium at the WSSNFH for endangered freshwater mussels residing in harms way of a bridge replacement in the Allegheny River. Approximately, 600 common mussels from two species sharing a similar reproductive strategy as target endangered species were salvaged in October, 2004; endangered mussels were salvaged in May 2005 as well. In August 2005, 450 common mussels were relocated to WSSNFH, and were included in a diet quality feeding study. Non-lethal and lethal measures of physiological activity and condition are used to monitor condition of common mussels.

After one year in captivity, short-term brooders have maintained condition and survival better than long-term brooders. Condition of *Elliptio dilatata* was not significantly different than wild *E. dilatata* in September 2005; whereas, captive *Actinonaias ligamentina* condition was significantly less than their wild counterparts. Endangered *Pleurobema clava* had higher survival (100%) than endangered *Epioblasma t. rangiana* (8%). Similarly, *E. dilatata* (74%) had higher survival than *A. ligamentina* (66%). Mussels collected in October 2004 were unusually low in physiological condition, and were likely stressed by high water conditions and high suspended bed loads in the Allegheny River throughout most of 2003 and 2004. WSSNFH modified culture systems in May 2005 to improve food delivery and food quality. Survival of endangered mussels brought into captivity in spring 2005 ranges 93%–100% for *E. t. rangiana* and *P. clava*. Captive care protocols developed from this effort will be available as conservation tools

in the future for mitigating loss of a resource due to in-stream activities.

TAQMAN® MGB REAL-TIME PCR APPROACH TO QUANTIFICATION OF *PERKINSUS MARINUS* AND *PERKINSUS SPP.* IN OYSTERS. Julie D. Gauthier¹, Chris R. Miller² and Ami E. Wilbur¹. ¹University of North Carolina, Center for Marine Science, ²Applied Biosystems.

Several molecular diagnostic assays have been developed in an attempt to replace the traditional Ray's Fluid Thioglycollate Medium (RFTM) assay for detection and quantification of *Perkinsus marinus* in oysters. Real-time PCR technology is now the state-of-the-art method currently used to diagnose disease intensity in vertebrates. We developed a simple (two-reagent) real-time PCR assay to quantify *P. marinus* (PMAR) and *Perkinsus spp.* (PERK) in oysters, using TaqMan® assays designed with Minor Groove Binder (MGB) probes on an Applied Biosystems 7500 Real-Time PCR System. This approach addresses several factors that can interfere with optimal real-time PCR performance. Both PERK and PMAR assays demonstrate strong correlations ($R^2 \geq 0.99$) between parasite cell density and real-time PCR threshold cycle (C_T) with amplification efficiencies $\geq 99\%$. The PERK assay results in similar amplification plots for the three species tested (*P. marinus*, *P. atlanticus* and *P. andrewsi*), whereas the PMAR assay reported only *P. marinus*. A strong correlation ($R^2 > 0.90$) was found between infection level determined by the traditional RFTM method and quantification by real-time PCR based on internal standards prepared from *P. marinus* spiked oyster tissue. The PCR assays also detected false negatives (15%) diagnosed by the traditional method. We demonstrate the usefulness of these assays in replacing the traditional method for a non-subjective, sensitive, specific and accurate quantification of *Perkinsus spp.* in oyster tissue, with particular application in analyzing frozen or archived material.

IS HABITAT AVAILABILITY LIMITING RECRUITMENT OF CALICO SCALLOPS (*ARGOPECTEN GIBBUS*)? Stephen P. Geiger, Janessa C. Cobb and Brett Pittinger. Florida Fish & Wildlife Research Institute, 100 8th Ave. S.E., St. Petersburg, FL 33701.

The Florida calico scallop fishery has declined from a peak of 42.7 million pounds of adductor muscle meats landed in 1984 to none landed in 2005. Removal of scallop and other shell as bycatch may have depleted the essential fisheries habitat for settling veligers. The goal of this study was to describe current abundance and distribution of scallops, shell, and associations between spat and its preferred substrate on two of the historic scallop fishing

grounds. Scallops were collected at 31% of the Atlantic stations, spat at 9%, and both calico scallop shell and other shell at 89%. Spat were most commonly found on scallop shells (46%), but were also found loose, on other shells, rocks and trash. Shell from other molluscs was 1.75 times as abundant as scallop shell. Potential predators that were abundant included *Astropecten articulatus*, *Portunus gibbesii* (also common in the Gulf) and *Distorsio clathrata*. Scallops were collected at 10% of the Gulf of Mexico stations, spat at 8%, scallop shell at 63%, and other mollusc shell at 71%. Rocks and hard bottom were common. Spat preferred other mollusc shells (64%) but were also found loose, on rocks, and on calico scallop shells. Shell from other molluscs was 20 times as abundant as scallop shell. Our findings suggest that the Cape Canaveral calico scallop bed currently has a similar spatial extent to historic records, and that calico scallops are seasonally abundant and are associated with shell deposits. The southwest Florida scallop bed is limited in extent and abundance.

INGESTION RATES AND LARVAL DEVELOPMENT OF ECHINODERMS ON NATURAL AND ARTIFICIAL PARTICLES. Sophie B. George, Biology Department, Georgia Southern University, P.O. Box 8042, Statesboro, GA 30460.

Ingestion rates and growth to metamorphosis for five species of echinoderm larvae were investigated in the laboratory using artificial and natural diets. The natural algal diets included *Dunaliella tertiolecta*, *Isochrysis galbana* and *Rhodomonas* sp., and the artificial diet used was a 10-fold diluted artificial feed made from Ziegler E-Z larval diet. The volume of cells ingested varied significantly among species, diets and larval age. All echinoderm larvae ingested significantly higher volumes of the larger alga *Rhodomonas* and the medium-sized alga *D. tertiolecta* than the artificial diet. Younger larvae ingested large and medium-sized particles at lower rates than older larvae. *Dendraster* larvae were more efficient at ingesting both the large and small particles and less efficient in ingesting the medium-sized particles compared to *Strongylocentrotus* larvae. The differences in ingestion rates among species might be due to differences in size, form, water velocity over the ciliated band, density of cilia on the ciliated larval band, and differences in size and palatability of the various diets. Though less of the artificial diet was ingested, *Lytechinus* and *Dendraster* larvae developed to metamorphosis at similar rates and attained similar sizes to those fed *D. tertiolecta* or the mixed algal diet of *I. galbana* and *D. tertiolecta*. An artificial feed would eliminate the need to culture phytoplankton and provide the potential of establishing nutritional requirements for echinoderm larvae. Increasing the size of the artificial particles to 300 μm for younger larvae and 600 μm for older larvae might lead to optimal ingestion rates and the production of large juveniles at metamorphosis.

THE EFFECTS OF DIETARY CHOLESTEROL AND PHOSPHOLIPIDS ON GROWTH AND PRODUCTION IN THE SEA URCHIN *LYTECHINUS VARIEGATUS*. Victoria K. Gibbs¹, Stephen A. Watts¹, Addison L. Lawrence², Mickie L. Powell¹, Hugh S. Hammer¹, Warren T. Jones¹ and John M. Lawrence³. ¹University of Alabama at Birmingham, 1530 3rd Ave. South, Campbell Hall, 374, Birmingham, AL 35294-1170, ²Texas A&M University System, ³University of South Florida.

Lipids are important components in the diets of marine organisms. In this study, the effects of dietary cholesterol and phospholipids were investigated for small *Lytechinus variegatus* to determine a requirement for either nutrient. *Lytechinus variegatus* ($n = 16$; average initial wet weight = 13.9 ± 0.15 g) were fed semi-purified formulated feeds supplemented to produce low, medium, or high levels of cholesterol (supplemented with 0, 0.3, or 0.6%, as fed) or phospholipids (supplemented at 0, 3, or 4%, as fed) for 12 weeks. Experimental levels of cholesterol and phospholipids were based on established requirements for marine invertebrates. Under the conditions of this study, dietary cholesterol did not have a significant effect on weight gain or gut or gonad production, although total production efficiency was lowest ($P = 0.007$) for individuals fed the low cholesterol feed (36.0, 47.6, and 41.9% for low, medium, and high levels, respectively). Individual weight gain and gonad production were highest for individuals fed the high phospholipid feed (final wet weight = 38.6, 40.3, and 45.8 g, $P < 0.001$; gonad wet weight = 5.3, 6.2, and 6.8 g, $P < 0.05$, for low, medium, and high levels, respectively). Total production efficiency was lowest ($P = 0.001$) for individuals fed the low phospholipid feed (35.1, 47.6, and 45.6%, respectively). However, organ production was not substantially affected by cholesterol or phospholipids when adjusted for total individual wet weight (ANCOVA $P > 0.05$). These data suggest that supplemental dietary cholesterol and phospholipids support weight gain in *Lytechinus variegatus*.

OPTIMIZING METHODS FOR DETECTION OF *CRYPTOSPORIDIUM* OOCYSTS IN NATIVE OYSTERS FROM THE CHESAPEAKE BAY. Autumn Girouard and Thaddeus Graczyk, Johns Hopkins Bloomberg School of Public Health.

Several groups have documented the presence of *Cryptosporidium*, an anthroponozoonotic enteric parasite, in oysters harvested for commercial purposes. Getting accurate estimates of *Cryptosporidium* contamination levels in oysters is difficult because recovery efficiencies are dependent on the isolation method used. Such estimates are important for determining the human health risks posed by consumption of contaminated oysters in a raw form. In this study, recovery efficiencies are compared for multiple methods used to isolate *Cryptosporidium* oocysts from experimentally contaminated oysters. Oysters were harvested after being allowed to filter oocysts from spiked aquarium water for approximately 24 hours. In one group, the entire oyster meat and all

hemolymph was processed by diethyl ether extraction followed by immunomagnetic separation (IMS) of oocysts from the resulting pellet. In another group, the oysters were dissected so that only gills, digestive diverticula and hemolymph were processed as described above. In the last group, oocysts were isolated directly from hemolymph alone by IMS. Recovered oocysts were enumerated by IFA. Recovery efficiencies for the methods described above were also determined using oyster tissue homogenate and hemolymph spiked with 1000 oocysts, to control for differences in recoveries related to differences in oocyst uptake rates among oysters. The results from this study will be used to determine the best method for quantifying *Cryptosporidium* levels in oysters collected from the Chesapeake Bay. This method would have broad application to native and non-native commercially harvested oysters and would be beneficial for regulatory agencies charged with determining safety of shellfish for human consumption.

INVESTIGATIONS INTO SOME EARLY-LIFE HISTORY STRATEGIES FOR CARIBBEAN SPINY LOBSTER AND IMPLICATIONS FOR PAN-CARIB CONNECTIVITY. Jason S. Goldstein¹, Mark J. Butler IV² and Hirokazu Matsuda³. ¹University of New Hampshire, ²Old Dominion University, ³MPIERC, Japan.

Worldwide, spiny lobsters possess extended larval periods that can easily exceed six months. During this protracted early-life history, pelagic larvae that are produced in one locality disperse throughout oceanic waters, and later settle in far-flung locations to grow and eventually support fisheries in their new home. Observations and limited empirical evidence suggest however that active behavior for Caribbean spiny lobster (*Panulirus argus*) larvae (phyllosoma) and postlarvae (pueruli) appears to have a significant impact on distribution and settlement. In support of this hypothesis, a series of laboratory studies were undertaken to more fully elucidate aspects of phyllosoma and pueruli responses to two selected cues, light and chemical cues, respectively. Phyllosoma culture experiments were initiated to quantify stage duration to the puerulus stage ($>175 \pm 30$ days after hatch (DAH)) as well as stage-specific differences (vertical movements) in response to simulated oceanic light. Two clear behavioral phototactic shifts to light were observed at ca. 60 and ca. 130 DAH using a custom-made light chamber. A complimentary series of laboratory experiments were carried out to test postlarval orientation and the potential for metamorphic delay in response to chemical cues characteristic of the nearshore nursery environment. Using field-caught animals, results showed that lobster postlarvae are attracted to coastal water as well as to the metabolites of red macroalgae ($n \approx 300$ trials) in laminar flow chambers. These findings coupled together enhance our understanding of the transport and settlement processes operating for this species throughout the Caribbean and will help to further validate oceanographic lobster models whose management implications are far reaching.

GENOMICS ON THE HALF-SHELL. Eric Edsinger Gonzales and Daniel Rokhsar, University of California, Berkeley, Berkeley, CA.

Sequencing of the human genome unveiled Life's working definition of *Homo sapiens*, making it tangible and discrete. Genomic tools and sequencing similarly transformed research in the models systems of development, medicine, and disease and in the process ignited the field of comparative genomics, a self-declared revolution that is now roiling its way across the Tree of Life. In the current third wave of genomics, the focus has been brought to bear on species that are of either phylogenetic or commercial and industrial importance, including model species in alternative energy, agriculture, and aquaculture. Though the revolution might not be televised, aquaculture genomics in bivalves will transform aquaculture and our understanding of its commercially important species, including the oyster *Crassostrea gigas*. As molluscs, bivalves are protostome lophotrochozoans and no fewer than six lophotrochozoan genomes are currently being sequenced. Our own favorite is the gastropod limpet *Lottia gigantea*. Numerous lophotrochozoan and molluscan genomic projects, including ESTs in *C. gigas*, have also been initiated, opening the door to their future genomic sequencing. Here, we review potential application of genomics to the field of aquaculture and how current cellular, biochemical, and ecological techniques can be expanded and integrated with genome-empowered approaches. We then focus on our current research in comparative genomics, looking at developmental patterning of the body plan, shell biomineralization, and metamorphosis in *L. gigantea* and *C. gigas*. Finally, we consider the environmental, economic, and cultural benefits and dangers of genetically modified organisms in aquaculture, a contentious issue that will inevitable be a focus in genomic aquaculture.

RECOVERY, BIOACCUMULATION AND INACTIVATION OF HUMAN WATERBORNE PATHOGENS BY *CRASSOSTREA ARIAKENSIS*. Thaddens K. Graczyk, Autumn S. Girouard, Leena Tamang, Sharon P. Nappier and Kellogg J. Schwab, Johns Hopkins Bloomberg School of Public Health, Baltimore.

Introduction of non-native oysters (i.e., *Crassostrea ariakensis*) into the Chesapeake Bay has been proposed as necessary for restoration of the oyster industry; however, nothing is known about the public health risks related to contamination of these oysters with human pathogens. Commercial size *C. ariakensis* triploids were maintained in large marine tanks with low (8 ppt), medium (12 ppt) and high (20 ppt) salinity water spiked with 1.0×10^5 of transmissible stages of the following human pathogens: *Cryptosporidium parvum* oocysts, *Giardia lamblia* cysts and microsporidian spores (i.e., *Encephalitozoon intestinalis*, *Encephalitozoon hellem*, and *Enterocytozoon bienersi*). Viable oocysts and spores were still detected in oysters on day 33 post water inoculation (pwi), and the cysts on day 14 pwi. The recovery, bioaccumulation, depuration,

and inactivation rates of human waterborne pathogens by *C. ariakensis* triploids were driven by salinity, and were optimal in medium and high salinity water. The concentration of human pathogens from ambient water by *C. ariakensis* and retention of these pathogens without (or with minimal) inactivation and a very slow depuration rate, provides evidence that these oysters may present a public health threat upon entering the human food chain if harvested from polluted water. This conclusion is reinforced by the concentration of waterborne pathogens used in the present study which was representative of levels of infectious agents in surface waters including the Chesapeake Bay. Aquacultures of non-native oysters in the Chesapeake Bay will provide excellent ecological services in regards to efficient cleaning of human infectious agents from the estuarine waters.

OFFSHORE MOLLUSCAN SHELL ACCUMULATIONS: OCEAN RUBBISH OR REFUGE? Kaitlin Graiff, Ray Grizzle, Holly Abeels, Jennifer Greene, Melissa Brodeur and Larry Ward. Jackson Estuarine Laboratory, University of New Hampshire.

Molluscan shell accumulations were mapped in a 400 km² study area in the western Gulf of Maine off the New Hampshire coast during 2004 using towed underwater video. These shell accumulations were mainly found along the edges of Jeffreys Ledge and were comprised of empty valves of the Atlantic surf clam (*Spisula solidissima*) and the ocean quahog (*Arctica islandica*). Although there has been little ecological research on offshore shell accumulations, they have been identified as potentially significant habitat for several fish species and invertebrates such as lobsters and crabs. Shell accumulations increase the complexity of the sea floor and potentially provide refuge from predators for juvenile life stages of finfish and invertebrates. Subtidal oyster shell (*Crassostrea virginica*) accumulations in southeastern U.S. estuaries are known to provide habitat for many species of commercially important fish and crustaceans. It seems reasonable to expect a similar ecological role for offshore accumulations of shells from other molluscs. Preliminary assessment of the video data from Jeffreys Ledge also indicates a possible relationship between burrowing “anemone forests” (cerianthids) and observed shell accumulations. Future work should explore the habitat value that offshore shell accumulations potentially have for managed species.

AQUACULTURE CAGE BIOFOULING IN THE GULF OF MAINE: HOW DOES THE BLUE MUSSEL (*MYTILUS EDULIS*) OUT-MUSCLE OTHER SPECIES? Jennifer Greene and Ray Grizzle, Jackson Estuarine Laboratory, University of New Hampshire.

Biofouling on naturally occurring hard substrates in the Gulf of Maine has been well documented, and a variety of biotic interactions as well as physical factors have been found to influence

settlement and successional patterns. The present study differed from all previous research in the region by focusing on large, offshore fish cages suspended above the seabed. The overall goal was to characterize development of fouling communities, while providing information for engineers and project managers. Biofouling, especially by heavier organisms like molluscs, adds weight and drag to fish cages, thereby reducing water flow and affecting its behavior in rough seas and high currents. Experimental panels were deployed at a depth of ~15 meters over four different time intervals, in replicates of four, over the course of one year. One set of panels was deployed for a full year, two sets for 6-months (beginning at different seasons), and four sets of 3-month (seasonal) panels. Each panel was constructed of a 10 × 10 cm piece of knotless nylon netting attached to a PVC frame. The fouling community that developed diverged from the pattern previously described for shallow water benthos, mainly because of the dominance of the blue mussel, *Mytilus edulis*, in nearly all seral stages as well as the climax (1-year) fouling community. Factors probably influencing this dominance included limited predator abundance, optimal growth conditions, and high reproductive rates.

DEVELOPMENT OF NOVEL TECHNOLOGIES TO COMBAT FOULING IN AQUACULTURE. Paul Gribben¹, Tim Charlton¹, Lachlan Yee¹, Rocky De Nys² and Peter Steinberg¹.

¹Centre for Marine Biofouling, University of New South Wales, Sydney, 2052, Australia, ²School of Marine Biology and Aquaculture, James Cook University of North Queensland, Townsville, QLD 4811, Australia.

Fouling of nets, pens, and buoys, and in some cases (shellfish) the organisms themselves, are a major problem for the aquaculture industry. In Australia, a conservative estimate of the costs of fouling to the industry is \$20–30 M, in lost production, cleaning and other labor costs, etc. The use of traditional solutions for fouling control (mostly derived from antifouling technologies for ships) is problematic in aquaculture systems because of environmental, health (proximity to food stuffs) and cost constraints. At the centre for Marine Biofouling and Bio-Innovation (University of New South Wales and the School of Marine Biology and Aquaculture (James Cook University)), we have been developing a variety of novel solutions for use in aquaculture. These have developed for a number of industry sectors, and span technologies that are being commercialised to those that are early stage experimental science. Early stage commercialisation technologies are heavy metal free, water based coatings using organic biocides for use on salmon cages and rapid dry coatings for direct application to pearl and edible oysters. New technologies under development include low cost coatings using deterrent surface properties, and living paints encapsulating marine bacteria.

IN SITU MEASUREMENTS OF SESTON UPTAKE BY CONSTRUCTED/RESTORED OYSTER REEFS IN SOUTH CAROLINA.

R. E. Grizzle¹, J. K. Greene², L. D. Coen³ and N. Hadley³. ¹Jackson Laboratory and Department of Zoology, University New Hampshire, 85 Adams Point Rd., Durham, NH 03824, ²Department of Zoology, University of New Hampshire, ³MRRI, South Carolina Department of Natural Resources.

One of the metrics that can be used to assess the success of restored oyster reefs is their effect on water quality. This presentation describes a novel technique we have developed to provide rapid assessment of seston uptake (removal) by dense populations of bivalve molluscs, focusing on data gathered during May 2005 from five shellfish reefs of different ages, bivalve densities, and other characteristics in South Carolina. The overall technique involved concurrent sampling upstream and downstream of each study reef with *in situ* fluorometers and pumped water for laboratory analyses. *In situ* fluorometry detected significant differences between mean upstream and downstream readings for all five reefs, with total seston uptake ranging from 1.9% to 23.1%. Laboratory analysis of chlorophyll *a* concentrations in pumped water samples taken concurrently with the *in situ* fluorometry data showed substantial variability between upstream and downstream data, except for one reef which indicated an overall 35% uptake rate (compared to 23.1% based on *in situ* fluorometry data). As a control, sampling over recently constructed reefs (shell only) did not result in any measurable seston loss from the water column. Our system is a fast and effective approach to quantifying seston removal, and when data are logged at short-term intervals (seconds) potentially provides information on variations in feeding rates and related processes typically only available in laboratory studies.

IMPACTS OF INVASIVE SPECIES ON NATIVE OYSTER RESTORATION IN CENTRAL CALIFORNIA.

Edwin Grosholz¹ and David Kimbro². ¹Department of Environmental Science and Policy, ²Bodega Marine Laboratory, University of California, Davis, CA 95616.

The invasion of non-native species in the coastal waters of the U.S. has had enormous impacts on community structure and ecosystem function. Invasive non-native species have been particularly problematic where attempts have been made to restore native species. We document the impacts of invasive predatory crabs and oyster drills on attempts to restore native Olympia oysters (*Ostrea conchaphila*) in the Tomales Bay estuary in central California. Our work shows that introduced European green crabs (*Carcinus maenas*) can have a significant predatory impact on outplanted juvenile oysters in field enclosure experiments and in experimental mesocosms. We also demonstrate that that introduced oyster drills (*Urosalpinx cinerea*) are also significant predators in both field experiments and mesocosm experiments. The distribution of these predators shows a strong density gradient with

the estuarine conditions in Tomales Bay and parallels an equally strongly gradient in recruitment, survival and growth of native oysters. We discuss the degree to which these introduced predators shape the population structure of native oysters and how they will influence future efforts to restore oysters in central California.

EARLY STEAMER CLAM (*MYA ARENARIA*) IN TWO COASTAL PONDS IN OAK BLUFFS, MA (MARTHA'S VINEYARD ISLAND).

David W. Grunden and Danielle Ewart, Shellfish Department, Town of Oak Bluffs, P.O. Box 1327, Oak Bluffs, MA, 02557.

The investigation into this project began in 2001 when the Town of Oak Bluffs purchased 200,000 seed (2–3 mm) steamer clams. Three trial restoration sites were chosen; two in Sengekontacket Pond and one in Lagoon Pond. One site in Sengekontacket Pond has remained open for harvest. The other two sites are alternated one opening every other year. All three sites are utilized primarily for recreational shellfishing, though occasionally a commercial shellfisherman does harvest from one of the sites in Sengekontacket Pond. The first year the steamer seed was only grown in the upweller and broadcast seeded at 12–15 mm. The seed at this size dug into the sandy substrate within 15 minutes. The area was marked but ice removed the marker that first winter. In subsequent years the Town of Oak Bluffs has been able to increase the amount of seed raised to 600,000 in 2005 (another 600,000 has been ordered for the 2006 season). The Town's Shellfish Department constructed sand filled nursery rafts to allow for greater growout of the seed. The seed steamers are still removed from the upweller once they reach 12–15mm, but are now transferred into the nursery rafts where they are held until late mid-September or early October. The seed measured 22.4–38.2 mm when they were planted out in the fall of 2005. The fishing effort has been monitored by the Shellfish Department and we have seen a modest increase in the steamer clam landings from these areas since the project began.

GENOME MAPPING IN THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA* GMELIN).

Ximing Guo, Yongping Wang, Ziniu Yu, Lingling Wang and Jeong-ho Lee. Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Ave., Port Norris, NJ 08349.

The eastern oyster, *Crassostrea virginica* Gmelin, is an important aquaculture species as well as a popular model species for molluscan research. The biology and ecology of the eastern oyster are well understood, but our knowledge about its genome remains limited. We have been developing tools and applying them in genome mapping in the eastern oyster. For physical mapping, we used fluorescence *in situ* hybridization (FISH) to characterize and map oyster chromosomes. Repetitive DNA sequences and genes were mapped to oyster chromosomes by FISH, and some revealed interesting features of the oyster genome. The chromosomal loca-

tion of rRNA genes, on the long arms of Chromosome 10 in Pacific species and on the short arms of Chromosome 2 in Atlantic species, provided an interesting divide between the Pacific and Atlantic species. Nine PI clones were mapped to seven of the ten oyster chromosomes. For linkage mapping, we developed over 600 amplified fragment length polymorphism (AFLP) markers and constructed four moderately dense linkage maps. We identified disease-resistance QTL by mapping markers that showed significant frequency shifts after disease-inflicted mortalities. Markers affected by diseases clustered together on genetic maps, and all affected markers within a cluster showed frequency shifts in the same direction. Mapping analysis in two families identified 12 putative Dermo/summer mortality-resistance QTL, and at least seven were independent. Microsatellites are being developed and mapped to increase the transferability of genetic maps and mapped QTL. Candidate host-defense genes are being mapped using single nucleotide polymorphism to detect possible linkage to disease-resistance QTL.

OYSTERS AND OYSTER FARMING IN CHINA: A REVIEW. Ximing Guo¹, Guofan Zhang², Lumin Qian³, Haiyan Wang¹, Xiao Liu² and Aimin Wang⁴. ¹Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Ave., Port Norris, NJ 80349, ²Institute of Oceanology, Chinese Academy of Sciences, PRC, ³Third Institute of Oceanology, Oceanic Administration, PRC, ⁴Ocean College, Hainan University, PRC.

In an effort to survey *Crassostrea ariakensis* populations in China, we conducted literature reviews and visited over 37 sites along China's coast. Here we present our findings about oysters and oyster farming in China in light of recent taxonomic revisions. Seventeen species of oysters have been reported along China's coast. Many of the species occur in southern China and are relatively rare. There is considerable confusion about the classification of *C. ariakensis* and three other species. Numerous oyster reefs, both ancient and living, exist along the coast, and *C. ariakensis* was present in all four live reefs that we saw. In three of the reefs, *C. ariakensis* is the dominant or founding species, where large oysters on the bottom are *C. ariakensis* and small oysters on top are other species. Oyster farming is primarily for *C. hongkongensis* in the south (Guangxi and Guangdong), *C. gigas* in the north (Shandong and Liaoning), and *C. angulata* in the middle (Fujian and Zhejiang). *C. hongkongensis*, also known as the white oyster or *C. rivularis*, is one of the most important species cultured in China. *C. hongkongensis* culture is based on natural seeds with one estuary in Guangxi supplying about 2.5 billion. Most of the published literature on *C. rivularis* from southern China is for *C. hongkongensis*, not for *C. ariakensis*, which is not intentionally cultured. It is present at low frequencies in natural *C. hongkon-*

ensis seeds and selected against by farmers. Pollution has devastated oyster populations in at least two estuaries.

TESTING DISEASE RESISTANCE IN OYSTERS: EXPERIMENTAL INFECTIONS WITH BACTERIAL PATHOGENS IN *CRASSOSTREA VIRGINICA* LARVAE AND SPAT. Javier Gómez-León¹, Dale Leavitt², Karen Tammi², Rachel Hadley¹, Luisa Villamil¹ and Marta Gómez-Chiarri¹. ¹University of Rhode Island, Department of Fisheries, Animal and Veterinary Science, 20A Woodward Hall, Kingston, RI 02881. ²Roger Williams University.

Culture of the eastern oyster (*Crassostrea virginica*) is a traditional activity that has great economical importance in the East Coast of USA and the Gulf of Mexico. Globally, shellfish production is often affected by bacterial pathogens, mainly *Vibrios*, which lead to high mortality rates in shellfish hatcheries. Another bacterial disease that has heavily impacted oyster culture in the Northeast US is Juvenile Oyster Disease (JOD), thought to be caused by *Roseovarius crassostreae*. In the present study, bacterial isolates that caused important mortalities in Pacific oyster larvae, RE22 and RE101, as well as an isolate from JOD-affected oysters (CV919-312) were used to perform experimental infections of oyster larvae and spat in order to determine differences in the susceptibility to bacterial infection of three oyster lines: a local Rhode Island line, a line resistant to Dermo and MSX (NEH), and a line resistant to JOD (FMF). All bacterial isolates tested were able to induce significant mortality in larvae and spat of *C. virginica*, reaching mortalities ranging from 50–100%. Differences in susceptibility between the lines were observed, with the NEH line showing the highest survival. Infected larvae exhibited abnormal circular swimming movements on their sides and deformed velum with cilia clumping. Factors affecting survival included temperature and size of the oysters. This research may provide a useful tool to test for disease resistance mechanisms in oysters.

EFFECT OF DIETARY PROTEIN ON CONSUMPTION, GROWTH AND PRODUCTION OF THE SEA URCHIN *LYTECHINUS VARIEGATUS*. H. Hammer¹, S. Watts¹, A. Lawrence² and J. Lawrence³. ¹Department of Biology, University of Alabama at Birmingham, ²Shrimp Mariculture Project, Texas A&M University, ³Department of Biology, University of South Florida.

Feeds that differ in protein concentration (17, 21, 25 and 31%, as fed) were formulated, cold-extruded and dried at 60°C to produce a dry pellet. Sea urchins ($n = 64$) were divided into four groups and placed individually into a semi-recirculating system at $32 \pm 2\text{‰}$ salinity and $22 \pm 1^\circ\text{C}$. Urchins were fed daily one of four diets *ad libitum* for 87 days. Consumption was measured daily; urchins were weighed and test diameters measured at days 0, 29,

57 and 87. At day 87, urchins were dissected and separated into components (test, lantern, gut and gonad) that were weighed, dried and reweighed. At days 0–87, urchins fed the 31% protein feed consumed less food than the other treatments. Urchins fed the 31% protein feed had a significantly greater body weight gain/day (1.3%) and test diameter (42.7 mm) than urchins fed the 17% (0.9%, 38.3 mm, respectively) or 21% protein feed (1.1%, 40.7 mm, respectively) but not the 25% protein feed (1.3%, 41.7 mm, respectively). Wet weight was significantly different among the treatments and varied directly with dietary protein (40.4, 37.0, 34.0, 28.6 g, respectively). Urchins fed the 31% protein feed had the highest production efficiency (48.1%) among the treatments (36.6, 32.5 and 24.8%, respectively). Gonad production efficiency in urchins fed the 31% protein feed (12.6%) was greater than urchins fed the 17% (6.9%) or 21% (9.4%) but not the 25% protein feed (10.7%). The 31% protein feed provided the best weight gain with the highest efficiency of the feeds tested.

DEMOGRAPHIC CHARACTERISTICS OF STABLE FRESHWATER MUSSEL POPULATIONS IN THE SOUTH-EASTERN UNITED STATES. Wendell R. Haag and Melvin L. Warren Jr., USDA Forest Service Center for Bottomland Hardwoods Research, 1000 Front St., Oxford, MS 38655.

Population dynamics of freshwater mussels are poorly known and represent a major information need for conservation of these imperiled animals. Most notably, the level of recruitment needed to maintain a stable mussel population is unknown, making it difficult to meaningfully assess the viability of a population. We measured annual recruitment and survivorship in two diverse mussel communities (Little Tallahatchie River, MS, and Sipsey River, AL) from 1999 to 2005. For all species, survivorship from glochidia to the recruit stage (benthic individuals approximately two to four months of age) was low (9.12×10^{-6} to 3.92×10^{-5}), but was high for all other life stages (0.63–0.95). Recruitment varied widely among species, sites, and years. For some species (e.g., *Amblema plicata*, *Elliptio arca*, and *Obovaria unicolor*), recruitment was sporadic, ranging from years with no detectable recruitment to years in which recruits composed >50% of the population. For other species (e.g., *Fusconaia cerina*, *Pleurobema decisum*, *Quadrula asperata*, and *Q. pustulosa*), recruitment occurred at a more constant level (0–15% of population). We used stochastic stage-based matrix population models based on observed demographic parameters to evaluate the potential influence of varying levels of recruitment on long-term population viability. These models predict that species with higher annual variability in recruitment require a higher mean recruitment level over time to maintain a stable population than species with less variable recruitment. Demographic differences among species show the existence of widely divergent life history strategies in freshwater

mussels and have important implications for the conservation of these animals.

IMPACT OF SEA OTTERS ON SHELLFISH FISHERIES AND AQUACULTURE IN B.C. CANADA. Rick Harbo, Linda Nichol, Laurie Convey, Jennifer Toole and Lieneke Marshall. Fisheries and Oceans Canada, 3225 Stephenson Point Rd., Namaimo, B.C., V9T 1K3, Canada.

Re-introduced sea otters have increased in number (>3,200 estimated in 2005) and expanded their range on the British Columbia coast, causing impacts on shellfish fishery resources. There have been concerns expressed by First Nations about the loss of access to clam, crab and sea urchin resources. The increase in kelp beds (a result of otter predation on urchins) has affected local navigation channels for small boats. A variety of commercial and recreational shellfish fisheries have been impacted by sea otters, including Dungeness crab, *Cancer magister*, red sea urchin, *Strongylocentrotus franciscanus*, Geoduck clam, *Panopea abrupta*, and Manila clam, *Venerupis philippinarum*. While otters are not the only cause of shellfish declines off B.C. (e.g., northern abalone, *Haliotis kamtschatkana*), predation by otters will keep shellfish abundances and sizes at levels that hinder the resumption of commercial fisheries. Sea otters have limited plans for geoduck aquaculture and enhancement on the west coast of Vancouver Island. There have been complaints about otter predation on some intertidal manila clam aquaculture tenures. To date, sea otters have taken little interest in Pacific oysters on intertidal or deep water aquaculture tenures. It is expected that conflicts will continue and increase in the next 10 years.

AGE AND GROWTH OF WILD CRASSOSTREA ARIAKENSIS AND C. GIGAS FROM LAIZHOU BAY, CHINA. Juliana M. Harding and Roger Mann. VIMS, P.O. Box 1346, Gloucester Point, Virginia, USA 23062.

Shell height at age estimates from Suminoe (*Crassostrea ariakensis*) and Pacific (*Crassostrea gigas*) oysters from a natural oyster reef in Laizhou Bay, China were compared with estimates from triploid *C. ariakensis* of known age from the Rappahannock River, Virginia. Both *C. ariakensis* and *C. gigas* reach shell heights in excess of 76 mm (3 inches) within two years after settlement regardless of the source location. This fast growth appears to continue through at least age four or age five in wild individuals as the growth trajectory for both species had not begun to flatten in the oldest individuals collected. Fitted growth curves were not significantly different between species within the same habitat, within species in different habitats or between species in different habitats.

TROPHIC CONSEQUENCES OF A LONG-LIVED NONNATIVE PREDATOR (*RAPANA VENOSA*) ON ESTUARINE COMMUNITY DYNAMICS. Juliana M. Harding and Roger Mann. VIMS, P.O. Box 1346, Gloucester Point, Virginia, USA 23062.

Veined rapa whelks, *Rapana venosa*, are large generalist predators with the potential to live in excess of 10 yrs and life history suitable for successful invasion of estuarine habitats. The presence of rapa whelks in a habitat has obvious consequences for the prey field in that rapa whelk prey consumption shifts ontogenetically from small (e.g., *Mytilus* sp., *Macoma* sp., *Mya* sp., *Crassostrea* sp.) to large (e.g., *Mercenaria* sp., *Crassostrea* sp.) prey. Laboratory and mesocosm experiments indicate that wild rapa whelks reach a size refuge from predation by blue crabs (*Callinectes sapidus*) within one year post settlement at critical sizes of 30–40 mm SL. At sizes >40 mm, rapa whelk distribution in Chesapeake Bay is probably limited only by salinity and food availability. The presence of large predators with the ability to repel competitors (blue crabs) on shared feeding grounds may force native species into habitat refugia delimited by salinity tolerances. Scenarios predicting relative abundance and competitive interactions between bivalve prey, rapa whelks, and blue crabs with impacts on trophic dynamics and habitat use are discussed.

GENETIC TRACKING OF RESTORATION OYSTERS TO GAUGE SUCCESS—A COST/BENEFIT ANALYSIS. Matthew P. Hare, University of Maryland.

Restoration of oyster stocks in Chesapeake Bay is a monumental task to which abundant resources have been committed and for which many dedicated parties have labored. Beyond establishing a ten-year goal for the increase of census numbers, little attention was initially paid to establishing rigorous benchmarks for success, or collecting data that could either measure small successes or determine the cause of failures. This has been changing more recently, but now most restoration effort is focused on targeted population supplementation using artificially selected, disease tolerant *C. virginica* to combat high mortalities from parasitic diseases. This tactic has potential benefits and considerable risks. I will argue that genetic testing of recruitment is necessary to evaluate and manage the genetic risks of supplementation with inbred oysters, but it also provides the most meaningful measure of overall restoration efficacy. Results will be presented from a highly collaborative effort to genetically monitor DEBY-strain restoration plantings in two Chesapeake subestuaries. The results indicate that the hatchery amplification of DEBY broodstock to produce restoration oysters is contributing to inbreeding in the oysters over and above that already realized during artificial selection. Also, the DEBY contribution to local recruitment in the Great Wicomico River in 2002 was approximately 10%, a result that belies appearances based on the number of DEBY oysters planted and the

elevated levels of recruitment that year. Inbreeding may or may not be the greatest risk facing restoration oysters and threatening restoration success, but only improved genetic testing will allow informed risk management.

METABOLIC RATES OF *CRASSOSTREA ARIAKENSIS* AND *CRASSOSTREA VIRGINICA* AT TWO TEMPERATURES AND THREE SALINITIES. Nicole Harlan, Kennedy Paynter and Donald Meritt. University of Maryland Center for Environmental Science.

Maryland and Virginia have proposed to replace the native oyster, *Crassostrea virginica*, with the suminoe oyster, *Crassostrea ariakensis*, in Chesapeake Bay. *C. virginica*, is highly tolerant of hypoxic conditions and can survive emersion or nearly anoxic seawater for days to weeks depending on the temperature. In order to replace *C. virginica*'s ecological niche of establishing vast benthic reefs in Chesapeake Bay, *C. ariakensis* may require similar tolerances. However, when the oysters were placed in sealed jars of anoxic water, *C. ariakensis* lived for an average of four days, while *C. virginica* persisted for more than fourteen days. Studies at 22°C have shown that the metabolic rate of *C. ariakensis* (1.96 ± 0.102 O₂/hr/gdw) is significantly higher than that of *C. virginica* (1.15 ± 0.079 mg O₂/hr/gdw; $p = 0.0244$). In order to better understand the aerobic requirements of these two species under different conditions, standard metabolic rates of each species were determined at two temperatures, 10 and 20°C, and three salinities, 5, 15, and 25 psu. At both temperatures and all three salinities, the metabolic rate of *C. ariakensis* was higher than that of *C. virginica*. Upon immersion in the test chambers, *C. ariakensis* gaped and began using oxygen within minutes, while *C. virginica* kept their valves shut for much longer. These data may influence the decision to use *C. ariakensis* as an ecological substitute for *C. virginica* in the Chesapeake Bay.

ANALYSIS OF ENZYME, CARBOHYDRATE AND MINERAL DISTRIBUTION IN THE FOOT OF ABALONE SHELLFISH. Leanne Harris, Helen Lambkin and Nuala O'Byrne-ring. Dublin Institute of Technology, Biological Sciences, Kevin Street, Dublin 8, Ireland.

The meat of the abalone shellfish has been labelled as a luxury food for thousands of years. The source of this epicurean delicacy is the foot, which is the most conspicuous external feature of this organism. The foot is a large muscular organ with an extensive nerve and vascular supply that serves both sensory and locomotory functions. The foot is also involved in many other functions such as locating and manipulating food, attaching eggs to substrates, cleaning the shell, finding potential mates and thwarting predators.

The foot is primarily made up of epithelial tissue, connective tissue and muscle. In this study the distribution of functional and structural elements was investigated in the pedal organ of two species of abalone, *Haliotis tuberculata* and *Haliotis discus hannai*. The pedal and peripheral epithelia expressed high levels of activity for the following enzymes: chloroacetate esterase, α -naphthyl butyrate esterase, alkaline and acid phosphatase, peroxidase and carbonic anhydrase. The sub-epithelial ganglion cells were positive for α -naphthyl butyrate esterase and acetylcholinesterase. Neutral mucins, acid mucins, carboxylated mucins and sulphated mucins were found in epithelial cells, in sub-epidermal gland cells and in the ground substance of the connective tissue and muscle. Melanin was identified in the sub-epidermal gland cells and in the pedal and peripheral epithelial cells. The basement membrane of the pedal epithelium was positive for calcium. A myriad of cell components and cellular activities in the tissues of the abalone foot were demonstrated, revealing cell types and reflecting the molecular pathways at work within these tissues.

DEVELOPMENT OF PCR TECHNIQUES FOR THE DETECTION OF *VIBRIO CARCHARIAE* AND *PERKINSUS OLSENI* IN ABALONE TISSUES. Leanne Harris, Fergus Ryan, Helen Lambkin and Nuala O'Byrnering, Dublin Institute of Technology, Biological Sciences, Kevin Street, Dublin 8, Ireland.

Global demand for abalone has significantly increased in recent years, however, wild stocks of abalone have declined in number, as a result of overexploitation and the spread of infectious disease. Disease outbreaks are recognised as a significant constraint to aquaculture production and trade that affects both economic development and the socio-economic revenue of many countries. Bacteria and protozoa are the most commonly encountered pathogens in abalone shellfish. *Vibrio harveyi/carchariae* is a highly pathogenic bacterium to abalone and *Perkinsus atlanticus/olseni* is a protozoan that also causes severe disease in this shellfish. Both pathogens are ranked amongst the top ten most significant disease causing organisms of abalone. In this study, a multiplex PCR method was developed to simultaneously amplify a 413 bp region of the 16S rRNA sequence of *V. carchariae/harveyi* and a 155 bp region of the actin mRNA gene sequence of *Haliotis* spp. This multiplex PCR was used to amplify these sequences in both fixed tissues and paraffin embedded tissues of infected *Haliotis tuberculata*. A primer set was designed to target a 245 bp region of the ITS sequence of *P. atlanticus* from paraffin embedded samples of infected *Ruditapes decussatus* which could be adapted to detect *P. olseni* in abalone tissues. Also quantitative PCR using these primers is a further potential development. These PCR protocols offer a rapid and specific method for the identification of *V. carchariae* and *P. olseni* in shellfish.

COMPARATIVE GROWTH AND SURVIVAL OF DIPLOID AND TRIPLOID SUMINOE OYSTERS, *CRASSOSTREA ARIAKENSIS*, IN MULTIPLE QUARANTINE SYSTEMS. Heather D. Harwell and Standish K. Allen Jr, Virginia Institute of Marine Science, P.O. Box 1346, Gloucester Point, VA 23062.

Much of the research on *Crassostrea ariakensis* has revealed superior growth rates and resistance to disease compared to the native oyster, *C. virginica*. All field studies of growth and survival have utilized sterile triploid oysters for reasons of biosecurity. Thus, triploids are serving as a surrogate for diploid performance in these field trials. A direct, simultaneous comparison of the growth and survival of diploid and triploid *C. ariakensis* is needed to refine population growth models based on triploid field data. Three replicate lines of diploid and triploid *C. ariakensis* were placed at four quarantine systems in Virginia and Maryland in December 2004. Individual repeated measures of subsets of oysters were gathered from monthly data on percent survival, wet weight, and shell length. In addition, quarterly estimates of condition index were obtained. Data gathered in this fashion will be used to determine a correction factor(s) that can then be applied to results from past studies of triploid *C. ariakensis* in order to refine models of potential population growth.

ROLE OF LOW SALINITY REFUGE IN REGULATING THE PREVALENCE OF THE PARASITE *LOXOTHYLACUS PANOPAEI* IN THE XANTHID *PANOPEUS OBESUS*. Lesli Haynes¹, S. Gregory Tolley¹, Aswani K. Volety¹ and James T. Winstead², ¹Florida Gulf Coast University, 10501 FGCU Blvd. S., Ft. Myers, FL 33965, ²United States Environmental Protection Agency.

This study was conducted to examine the potential influence of salinity, a proxy for freshwater inflow, on the prevalence of the castrator parasite, *Loxothylacus panopaei*, on mud crabs found on Southwest Florida oyster reefs. Spatial and seasonal patterns of the presence of potential host crabs and the prevalence of the parasite were assessed in the Caloosahatchee, Estero, and Faka-Union estuaries of Southwest Florida. Lift nets (1 m²) containing five liters of oyster clusters were deployed on intertidal reefs at three sites along the salinity gradient of each estuary. Nets were deployed during three seasonally dry and three seasonally wet months for a period of 30 d. Although *Panopeus obesus* were collected at all three locations within each estuary, densities tended to increase downstream in higher salinity waters. Parasite prevalence decreased at the upper stations in each estuary, was reduced during wet months compared to dry months, and was lower for those estuaries that experienced high levels of freshwater inflow. Furthermore, parasite prevalence was positively correlated with the mean salinity at capture of host crabs. Based on the distribution of *P. obesus* and the above patterns related to salinity, it appears that freshwater inflow and seasonal rains might regulate the prevalence

of this castrator parasite in Southwest Florida by creating spatiotemporal, low salinity refuge for its host.

MAPPING GENES AFFECTING SHELL COLOR AND SHAPE IN THE PACIFIC OYSTER *CRASSOSTREA GIGAS*.

Dennis Hedgecock¹, Philip Grupe² and Marie-luise Voigt³.

¹Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0371, ²Department of Biological Sciences, St. Olaf College, Northfield, MN 55057, ³Department of Cytogenetics, Leibniz-Institut für Plant Genetics and Crop Plant Research, Corrensstraße 3, D-06466m Gatersleben, Germany.

Variation in the color and shape of oyster shells is widely believed to be environmentally determined. However, Brake et al (2004 *Aquaculture* 229:89) recently provided evidence that shell and mantle edge color in the Pacific oyster, *Crassostrea gigas*, are heritable. We observed variation in shells of an F₂ family of Pacific oysters that appeared to be inherited, and we tested this hypothesis by statistical analyses and genetic mapping. Measures of shell shape, size and color were made from digital photographs of 179 oysters, using ImageJ software. Principal component analyses were used to consolidate the measured traits, and mapping was done on both principal components and some of the original individual traits. Mapping was made possible by a previously compiled linkage map for this same family of oysters, comprising 59 microsatellite DNA markers on 11 linkage groups. Using an interval mapping method, we identified a quantitative trait loci (QTL) for pigment saturation of the left valve on linkage group VIII, between *ucdCgi183* and *ucdCgi184*; genotypes at *ucdCgi183* explain 32% of shell color variance. Similarly, we identified two QTL for a pronounced left bend in some anteriorly viewed valves ("hook hinge") on linkage group III, in the adjacent intervals of *cmrCgi-ucdCgi198-imbCgi49*; genotypes at *ucdCgi198* explain 32% of hook hinge variance. Left hook hinge appears to be recessive, while shell pigmentation is nearly additive. These observations suggest that genes, as well as environment play, a role in determining the color and shape of oyster shells. Markers associated with these QTL could be used to breed oysters with more desirable shell characteristics.

BIVALVE SHELLFISH CAN BE VECTORS OF TRANSPORT OF HARMFUL ALGAE. Hélène Hégaret¹, Sandra E. Shumway¹ and Gary H. Wikfors².

¹Department of Marine Sciences, University of Connecticut, Groton, CT 06340, ² NOAA-NMFS, Milford, CT 06460.

Commercially-exploited bivalve molluscs are moved from one body of water to another for different purposes. Our study is testing the hypothesis that harmful algae can be introduced into new environments by means of these shellfish relocations. We identified which managed shellfish species and HABs co-occur geographically and established an experimental protocol to screen

shellfish-HAB pairs for consumption of the algae and release of living propagules after removal from the HAB exposure. Several cultured strains of harmful algae, such as *Prorocentrum minimum*, *Alexandrium fundyense*, and *Heterosigma akashiwo*, were fed to various species of bivalve molluscs, *Crassostrea virginica*, *Argopecten irradians*, *Mercenaria mercenaria* and *Mytilus edulis*, to assess the ability of the algal cells to pass intact through the digestive tract and subsequently grow. Ten bivalves of each species were also exposed for two days to a simulated harmful algal bloom at a natural bloom concentration. The algae were removed after two days of exposure, and the bivalves were kept for two more days in ultrafiltered seawater. Biodeposits were collected and observed under the microscope after 24 and 48 additional hours to evaluate the presence or absence of intact, viable cells or temporary cysts of the algae. Subsamples of biodeposits were transferred into algal culture medium and filtered seawater and monitored microscopically for algal growth. Intact algal cells of *P. minimum*, *A. fundyense*, and *H. akashiwo* were seen in biodeposits: generally these re-established growing populations.

EFFECT OF *IN VITRO* INTERACTIONS BETWEEN *MERCENARIA MERCENARIA* HEMOCYTES AND SEVERAL SPECIES OF HARMFUL ALGAE. Hélène Hégaret¹, Gary H. Wikfors², Madeleine Gonçalves³ and Sandra E. Shumway¹.

¹Department of Marine Sciences, University of Connecticut, Groton, CT 06340, ²NOAA-NMFS, Milford, CT 06460, ³IUEM-UBO, Technopole Brest-Iroise, 29280 Plouzané.

Shellfish species are very often exposed to harmful algal blooms (HABs), which can have noxious effects. The northern quahog (= hard clam), *Mercenaria mercenaria*, can experience blooms of several HAB species, such as *Prorocentrum minimum*, *Heterosigma akashiwo* or *Alexandrium fundyense*. *In vitro* tests of interactions between those harmful algae and *M. mercenaria* hemocytes have been conducted, measuring possible differences in hemocyte parameters attributable to harmful algae and measuring also the effect of hemocytes on the algae themselves. Indeed, the purpose of these experiments was to understand the possible roles of the hemocytes in bivalve responses to HABs, and how the algal cells are affected by these responses. Using microscopic and flow-cytometric observations, changes in morphology and physiology of the hemocytes, and of the algal cells, were assessed. In hemocytes, changes in hematology and physiology, including cell concentration, mortality, phagocytosis, adhesion, apoptosis and oxidative burst response, were determined. Changes in the physiology and the characteristics of the algal cells were determined as well: mortality, size, chlorophyll fluorescence, and internal complexity. The results show differences in the hemocyte responses when exposed to the several harmful algae tested. Examples of hemocyte responses include phagocytosis of algal cells or adhesion around cells, with attendant increases in dead, achlorotic algal cells. Thus, *in vitro* tests allow a better understanding of the role of

the hemocytes and the hemolymph in the defense mechanisms in molluscan shellfish to harmful algal cells.

DEVELOPMENT AND APPLICATION OF MICROSATELLITE MARKERS TO DETERMINE THE IMPACT OF RESTORATION OF THE BAY SCALLOP. Elizabeth Hemond and Ami E. Wilbur, University of North Carolina Wilmington, Department of Biology and Marine Biology, 601 S. College Rd., Wilmington, NC 28403.

A number of marine species, including the bay scallop (*Argopecten irradians*), are being restored using aquaculture-propagated broodstocks. Because these projects are laborious and expensive, it is important to be able to quantify the impact of these restorations. Natural genetic variation within species can be used to distinguish between the progeny of native populations and restoration stocks and thereby quantify the relative impact, provided sufficient genetic markers are available, and that the native and restoration stocks are differentiated to some degree. To facilitate these efforts, we have developed a set of microsatellite loci for bay scallops. Microsatellites are highly polymorphic, tandemly repeated sequences of two to six nucleotides dispersed throughout the genome of most eukaryotic organisms. Due to their number and variability, microsatellites are a powerful tool for identifying differences among populations (even individuals) and when used in conjunction with multi-locus analytical methods can provide the requisite discrimination needed to quantify the impact of restoration. We have isolated 19 trinucleotide and 41 tetranucleotide microsatellite loci and are in the process of characterizing the markers with respect to the level of polymorphism exhibited, presence of null alleles, and fidelity of inheritance. Preliminary data on four loci (AICL112, AICL115, AICL131, and AICL271) revealed extensive polymorphism (37, 14, 17 and 10 alleles, respectively) in two populations from Florida (Anclote Estuary and Pine Island Sound), but surprisingly little differentiation between locations (Monte Carlo χ^2 , allele frequency distribution, $p > 0.05$). Results from additional loci will be presented and the utility of these markers in assessing restoration will be discussed.

MANGROVE OYSTERS AS BIOINDICATORS IN SUB-TROPICAL DRY CLIMATES. Heidi Hertler¹, Lindsay Martinez¹, Danielle Kreeger² and Graciela Ramirez-Toro¹. ¹Inter-American University of Puerto Rico, ²Partnership for the Delaware Estuary.

Marine systems of the Caribbean are increasingly impacted by changes in land use. Escalating development is in many places out-pacing the ability of existing upland, salt flats, and mangroves to intercept sediment and nutrient runoff flowing toward the adjacent marine system. Elevated concentrations of chlorophyll-*a* and total suspended solids were correlated with land development in Southwest Puerto Rico. However, a direct cause and effect

relationship has not yet been established between development on the land and water quality degradation in the adjacent marine community. Suspension-feeding bivalves are regarded as excellent bioindicators of water quality, but they have not been studied in this context in tropical waters. We examined the population size structure and physiological condition of mangrove oysters, *Crassostrea rhizophorea*, along a gradient of land development in Southwest Puerto Rico in a first step towards using this species as a bioindicator of water quality in sub-tropical environments. Data suggest that *C. rhizophorea* fares better in undisturbed, clearer water rather than in eutrophied areas near development where food availability may be greater. In addition, oyster health, as measured by condition index, was inversely correlated with increasing land use. Thus, physiological measures of *C. rhizophorea* fitness may be useful indicators of ecosystem integrity.

CAN HARD CLAM LARVAL SURVIVAL EXPLAIN RECRUITMENT FAILURE IN GREAT SOUTH BAY: A MODELING STUDY? Eileen E. Hofmann¹, Eric N. Powell², John M. Klinck¹, John N. Kraeuter², Rebecca Marzec² and V. Monica Bricelj³. ¹Old Dominion University, ²Haskin Shellfish Research Laboratory, Rutgers University, ³Canada Natural Resources Council.

A biochemically-based model was developed to simulate the growth, development, and metamorphosis of hard clam (*Merccenaria mercenaria*) larvae. Larvae are simulated in terms of protein, neutral lipid, polar lipid, carbohydrate, and ash content. Initial biochemical content of the larva is determined by egg composition and changes in this occur as the larva grows and in response to the biochemical composition of available food. Simulations that used environmental conditions from Great South Bay, Long Island showed that variations in temperature and food quantity produce small changes in overall larval survivorship relative to that obtained from average conditions. The largest decrease in larval survivorship resulted from variations in the quality of food available to the larva. Reductions in food lipid content resulted in lowest larval survival rate. These results suggest that changes in food quality during the past decade may be a contributing factor to the present low recruitment rates of hard clam larvae in Great South Bay.

LINKING MARINE PATHOGENS TO MOLLUSCAN SHELLFISH: THE ECOLOGICAL ROLE OF MARINE AGGREGATES. Bridget A. Holohan¹, M. Maille Lyons¹, J. Evan Ward¹, Roxanna M. Smolowitz², Kevin R. Uhlinger², Joseph J. Vallino² and Bassem Allam³. ¹University of Connecticut, Department of Marine Sciences, 1080 Shennecossett Rd., Groton, CT 06359, ²Marine Biological Laboratory, Woods Hole, MA, ³Stony Brook University.

Benthic suspension-feeding invertebrates, such as bivalve molluscs, are constantly exposed to settling aggregates and the variety of microorganisms they contain. Recent research in our laboratory

demonstrates that aggregates can be a source of food particles as well as a reservoir for disease organisms. The field portion of this project is part of a large collaborative study that is addressing the ecological role of marine aggregates as a link between oysters (*Crassostrea virginica*) and the pathogen *Perkinsus marinus* and between northern quahogs (*Mercenaria mercenaria*) and the pathogen Quahog Parasite Unknown (QPX). Reference sites with low or no mortalities from these pathogens are located in Connecticut. Disease sites are located in Massachusetts and New York. At all sites, aggregate samples are collected using settling cones for the determination of the presence and concentration of pathogens. Concurrently, suspended aggregates are recorded *in situ* using a video camera focused on a stationary grid that is mounted within centimeters of the camera lens. The size and number of aggregates are determined using an image analysis program. Temperature, salinity, water depth and tidal stage are also recorded to evaluate correlations among aggregate characteristics (number and size), environmental parameters and pathogen presence. A summary of year one samples, taken from April through November, 2005 will be presented.

AUTOGENIC ECOSYSTEM ENGINEERS AND THE INFLUENCE OF HABITAT COMPLEXITY ON INTERTIDAL MIGRATIONS BY A TRANSIENT PREDATOR. Kirstin K. Holsman, P. Sean McDonald and David A. Armstrong. School of Aquatic and Fishery Sciences, UW.

Autogenic ecosystem engineers, which physically alter the systems they inhabit, have cascading impacts on various organisms. There are numerous examples of elevated densities within complex habitats created by native, naturalized, and exotic engineering species, yet the facilitative effects of these engineers depends on landscape patterns of their distribution as well as the size of the associated biota. Positive effects of increased physical structure often benefit small resident invertebrates while inhibiting larger transitory species. In this study, we examined how physical structure along a gradient of habitat complexity influences patterns of migration and habitat use by a transient benthic predator, Dungeness crab (*Cancer magister*). In particular, we compared crab habitat use of unstructured littoral habitats (ULH), native eelgrass beds (*Zostera marina*), naturalized Pacific oyster beds (*Crassostrea gigas*), and invasive *Spartina alterniflora* patches in Willapa Bay, WA. Baited trap surveys on ULH yielded catches of subadult *C. magister* 30–95% higher than catches from eelgrass beds, oyster beds, and meadows of *S. alterniflora*. Ultrasonic telemetry observations suggest that subadult *C. magister* making nighttime foraging incursions prefer ULH to other littoral habitats, and underwater video observations show that migrations are influenced by tidal rhythms since movements are correlated with the direction and velocity of current flow. The architecture of complex habitats

negatively influences *C. magister* utilization of littoral habitats, and ULH may be the primary foraging areas for migrating crabs. Since daily intertidal forays largely subsidize subtidal crab populations, ULH are particularly critical to crab production in these systems.

ARE TRIPLOID HARD CLAMS RESISTANT TO FLORIDA SUMMER STRESSORS? RESULTS OF LABORATORY CHALLENGES. Elise Hoover¹, Shirley Baker¹, John Scarpa² and Leslie Sturmer³. ¹University of Florida, Fisheries and Aquatic Sciences, ²Harbor Branch Oceanographic Institution, ³University of Florida, Cooperative Extension.

The hard clam, *Mercenaria mercenaria*, is an important aquaculture species in the state of Florida with \$12.9 million reported sales in 2003. Recently, clam farmers in southwest Florida have experienced high clam mortalities during the summer months. Clams may be experiencing heightened physiological stress due to an initial reduction in biomass from a spring spawning event, followed by increasing temperatures, fluctuating salinities and low dissolved oxygen levels. Triploid clams offer a potential solution to this problem as they are functionally sterile and therefore should have more energy available to survive these summer stressors. Triploidy was induced in the hard clam, *M. mercenaria*, by suppressing polar body I or II formation in fertilized eggs with cytochalasin B. Survival of triploid and diploid clams will be compared in laboratory challenges as part of a larger project to determine if there is a potential use for triploids in aquaculture. Laboratory challenges will combine typical southwest Florida conditions in a 3 × 2 factorial design. Water temperatures will be held at 32°C (90°F) in all treatments. Clams will be challenged with salinities of 15 ppt, 25 ppt, and 40 ppt and dissolved oxygen will be maintained at either normoxic or hypoxic levels. These lab-based challenge experiments will aid in determining if triploids are more stress resistant compared to diploids, thus increasing survival.

JUVENILE CHINOOK SALMON *ONCORHYNCHUS TSHAWYTSCHA* UTILIZATION OF LOW-INTERTIDAL EELGRASS AND OYSTER AQUACULTURE BEDS. Geoff Hosack¹, Brett Dumbauld², Ian Fleming³ and David Armstrong⁴. ¹Oregon State University, ²USDA-ARS, ³Memorial University of Newfoundland, ⁴University of Washington.

Estuaries function as nursery habitats for Pacific salmon populations by providing juvenile outmigrating salmonids with refugia from predators and trophic resources. Intertidal habitat in estuaries along the west coast of the U.S. is often modified by the addition of live oysters in aquaculture operations, which have become important economic contributors to small coastal economies. To as-

sess the importance of low-intertidal habitats for juvenile Chinook salmon, we compared the diet and distribution of Chinook in on-ground oyster aquaculture beds (*Crassostrea gigas*) with that in seagrass *Zostera marina* ("eelgrass") and unvegetated mudflat. We used a modified tow net to compare densities and collect diets of juvenile Chinook salmon (65–115 mm FL) in Willapa Bay, Washington. Using laboratory mesocosms, we evaluated which of these intertidal habitats are preferred by juvenile Chinook as refugia from predators. Field results suggested that outmigrating smolts did not exhibit a strong habitat preference since diet composition was unrelated to habitat type at the point of capture, and densities were significantly related to broad spatial patterns in the estuary but not habitat type within the low-intertidal zone. Older Chinook smolts (81–115 mm FL) in summer laboratory experiments significantly preferred eelgrass to mudflat or oyster in the presence of a mock avian predator while younger Chinook in spring (42–80 mm FL) demonstrated no significant change in habitat preference. This suggests that Chinook may not always exhibit strong habitat specificity, but structured intertidal habitats may provide important resources such as movement corridors on a broad landscape scale.

STATUS, TRENDS AND RESTORATION PLANNING FOR FRESHWATER MUSSELS OF THE COLUMBIA BASIN/ PACIFIC SLOPE: THE CTUIR MUSSEL PROJECT.

Jeanette Howard, Jayne Brim Box and David Wolf. Confederated Tribes of the Umatilla Indian Reservation, 73239 Confederate Way, Pendleton, OR 97801.

The Freshwater Mussel Project of the Confederated Tribes of the Umatilla Indian Reservation (CTUIR), the first program of its kind in the West, explores new ground in the restoration of freshwater mussels. The project began in 2003, and expands on the Tribe's overall goal of recovering an intact, fully functioning, Umatilla River. Freshwater mussels were vital components of stream ecosystems in the Columbia River Basin that have been affected directly and indirectly by dams, habitat deterioration, and declines in salmon populations. Mussels were also culturally and traditionally important to Native Americans in the region. Yet, prior to this study, little was known about the distribution or status of mussel populations in the region. The overall goal of CTUIR's mussel project is to provide essential information for designing a recovery plan in the Umatilla River and other Columbia subbasins where mussels may be declining or extinct. However, this cannot be accomplished without first better understanding habitat and host fish requirements, genetic diversity, functional role, population structure and historic distribution. In this presentation, I will summarize current efforts of the CTUIR Freshwater Mussel Project to fill knowledge gaps, including: the historic and current status and distribution of freshwater mussels in CTUIR's rivers of interest; habitat variables controlling distribution; preliminary information on the functional role of freshwater mussels in these systems; host fishes and timing of reproduction. In addition, I will discuss cur-

rent efforts underway to develop an ecologically based biomonitoring program using mussels as sentinel bioindicators in the Columbia Basin.

OREGON'S CLATSOP BEACH RAZOR CLAM FISHERIES: PAST, CURRENT AND THE FUTURE. **Matthew Hunter,** Oregon Department of Fish and Wildlife.

In Oregon, the 18-mile stretch of shoreline, known as the Clatsop Beaches, extends from the South Jetty of the Columbia River south to Tillamook Head. Over 90% of Oregon's razor clam catch and effort occurs in this area. This area has had a fishery since the turn of the century and it is where the majority of biological information, recreational and commercial fishery data has been collected. Historically, the fishery has been sampled on low-tide series during the spring and summer months and as weather permitted the rest of the year. Recreational digging effort from 1995–2004 averaged 62,700 digger trips per year with a record high in 2004 of 157,000. Commercial participation from 1995–2004 averaged 125 individuals with a high of 255 individuals in 2002. The total annual harvest from 1995–2004 averaged 896,000 clams with a record harvest in 2002 of 2,660,000 clams. The Pacific razor clam is considered to be the finest food clam on the west coast resulting in the harvest being a popular tradition among coastal and inland residents. Due to this popularity, user group conflicts, harvest pressure and expectations of a sustainable fishery resource pose the continual need for the best science available to construct framework of management decisions. Many regulation changes have occurred in the past five decades as a reaction to fishery issues. With the requirement of a recreational shellfish license in 2004, funds are available and ODFW shellfish staff hope to provide proactive management to eliminate future fishery issues.

ENVIRONMENTAL EFFECTS ON SEA URCHIN ROE ENHANCEMENT—A PIECE OF THE PUZZLE! **Phil James,** National Institute of Water and Atmospheric Research, P.O. Box 14-901, Kilbirnie, Wellington, New Zealand.

The effects of various environmental conditions on the development of urchin gonads have been examined in relation to roe enhancement (fattening) of wild caught sea urchins (*Evechinus chloroticus*) in New Zealand.

The effects of wave and feeding disturbance were measured by holding urchins in sea-cages suspended from a surface line (wave disturbed) or subsurface buoyed from a bottom line (not wave disturbed) and fed and cleaned *in situ* underwater or removed from the water for feeding and cleaning. Increased water movement in the wave disturbed cages resulted in a higher GI in these urchins compared to urchins in cages that were sub surface buoyed. Feeding disturbance had no effect on the GI values or colour quality of the urchin gonads, regardless of the disturbance treatment. An experiment to measure the effects of seasonality and the initial

gonad condition on roe enhancement has shown that it is possible to significantly increase the amount of roe in a relatively short period throughout a 12 month period and that the initial condition (GI) of the urchins has a significant effect on the efficacy of roe enhancement.

EFFECT OF DIETARY SELENIUM ON THE SEA URCHIN *LYTECHINUS VARIEGATUS*. Warren T. Jones¹, Mickie L. Powell¹, Victoria K. Gibbs¹, Hugh S. Hammer¹, John M. Lawrence², Addison L. Lawrence³ and Stephen A. Watts¹.

¹University of Alabama at Birmingham, UAB Biology CH374, Birmingham, AL 35294-1170, ²University of South Florida, ³Texas A&M University.

Selenium is an essential micronutrient in the diet of many animals; however, high levels may be toxic. In mammals, selenium is an important antioxidant, working with vitamin E to protect cell membranes and prevent free radical generation. Small *L. variegatus* (ca.15.5 g initial wet weight) were fed formulated feeds with low, medium, and high levels of selenium for 12 weeks (calculated at 0.23, 0.91, and 2.5 ppm; levels based on previously established dietary levels for other marine invertebrates, supplemented as Na₂SeO₃). Consumption was measured daily, and urchins were weighed and test diameters measured at 4-week intervals. Wet weights of individuals fed the high selenium feed were 12% lower ($p = 0.006$) than those fed the low and medium levels (43.11 ± 1.21 , 43.03 ± 1.22 , and 37.81 ± 1.37 g wet weight for low, medium, and high, respectively) of dietary selenium at 12 weeks. Urchins fed the low selenium feed had higher specific growth rates between four and eight weeks (1.5 vs. 1.2 and 1.1% body wet weight gain/day for low, medium and high levels, respectively). Additionally, test diameters for urchins fed the low and medium selenium feeds were slightly higher ($p = 0.077$) than those fed the high selenium (43.2 ± 0.39 , 43.2 ± 0.50 , and 41.8 ± 0.51 mm, respectively) feed. Feed consumption rates were similar among treatments suggesting weight gain was affected by other physiological mechanisms. Although no mortalities were observed, noticeable pathologies were found in the urchins fed high selenium feeds. These results suggest dietary toxicity at high levels of selenium.

DEVELOPMENT OF SINGLE NUCLEOTIDE POLYMORPHISMS (SNPS) IN *CRASSOSTREA ARIAKENSIS* AND RELATED *CRASSOSTREA* SPECIES. Hyungtaek Jung¹, Woojin Kim² and Patrick Gaffney¹. ¹University of Delaware, Graduate College of Marine Studies, Lewes, DE 19958, ²National Fisheries Research and Development Institute.

As a candidate for deliberate introduction into Atlantic waters, the Suminoe, or jinjiang oyster, *Crassostrea ariakensis*, has recently been the subject of intense interest, with particular focus on its ecology, taxonomy and population genetics. Because the tax-

onomy of the Asian *Crassostrea* is still incomplete and identification on morphological grounds is difficult, a suite of genetic markers suitable for identifying species and subspecies is needed. Such markers will allow screening of candidate source material, allow development of genetic signatures of hatchery strains for evaluating introductions, and ultimately provide tools for selective breeding and pedigree monitoring. We have tested primers originally designed to amplify fragments of known genes (Type I markers) in *C. gigas* for their ability to amplify putative homologs in the related Asian species *C. angulata*, *C. ariakensis* and *C. hongkongensis*. Of 16 loci developed for *C. gigas*, all amplified successfully in *C. angulata*, 15 amplified in *C. ariakensis* and 14 amplified in *C. hongkongensis*. In contrast, only five loci could be amplified in the Atlantic species *C. virginica*. Direct sequencing of amplicons revealed multiple intraspecific and interspecific candidate polymorphisms, and provided tools for genetic identification, linkage mapping, pedigree monitoring and phylogenetic analysis.

INGESTION OF MARINE AGGREGATES BY SUSPENSION-FEEDING MOLLUSCS. Dustin Kach and J. Evan Ward. University of Connecticut, Department of Marine Sciences, 1080 Shennecossett Rd., Groton, CT 06359.

A large body of literature focuses on suspension-feeding processes of molluscs, including the efficiency of particle capture. Bivalves, for example, capture individual picoplankton cells (0.2–2.0 μm) with a retention efficiency of less than 50%, leading to the assumption that such particles are not an important food resource. Picoplankton, however, are often concentrated within aggregates of much larger size. This study builds on our preliminary results and further investigates the ability of suspension feeders to ingest pico-particles (<2 μm) bound in aggregates. We fed the mussel, *Mytilus edulis*, the scallop, *Argopecten irradians*, and the slipper snail, *Crepidula fornicata*, 1 μm fluorescent beads that were (1) evenly dispersed in seawater, or (2) embedded within laboratory-made aggregates. Dispersed 10 μm beads were also delivered so that feeding activity could be determined. All feces were collected over 48 hr period, digested in sodium hydroxide (NaOH), and the fluorescent activity measured by a spectrophotometer. The number of beads ingested was then calculated using a previously established standard curve. Results indicate that aggregates significantly enhance the ingestion of 1 μm beads by all three animals. Differences among species in their ability to ingest aggregates and pico-particles, however, were evident. When feeding on aggregates, mussels demonstrated a ten fold increase in the number of 1 μm beads ingested. Compared to mussels, scallops ingested fewer aggregates, and slipper snails ingested more dispersed beads. These differences may be a consequence of variations in gill structure and mechanisms of particle processing. Our data suggest that aggregates allow suspension feeders to utilize embedded particles as food.

IDENTIFICATION OF GROWTH BANDS IN COCKLE, *FULVIA MUTICA* SHELLS IN KOREA. Do-hyung Kang¹, Heung-sik Park², Chris A. Richardson³ and Kwang-sik Choi¹.

¹Cheju National University, College of Marine Science, School of Applied Marine Science, 1 Ara 1 Dong, Jeju City, Jenu-Do 690-1786 Republic of Korea, ²Korea Ocean Research & Development Institute, ³University of Wales, UK.

This study reports identification of annual growth bands recorded in shell from cockle, *F. mutica* (Bivalvia: Cardiidae) collected from Jukdo, Korea. The growth lines were identified using acetate peel replicas of the shell sections. Total number of growth lines and distance (i.e. growth interval) between inter-growth lines were assessed using image-processing software. Age of the cockle was estimated by counting the number of each dark band in sectioned shell and umbo. Periodicity of the light and dark bands was compared with the daily water temperature data of the sampling area retrospectively. A total of 790 growth lines were identified from the umbo. Age of the cockle used in the analysis was predicted to be 6.5 year. The maximum distance (23.4 μm) and the minimum distance (1.2 μm) were found in a 3-year-band and in a 6-year-band, respectively. Average distance of the cockle was highest in 3-year-band. Periodicity of the bands was closely corresponded with temperature data, suggesting that retrospective technique was suitable for aging of the cockle.

MICROGROWTH BANDING PATTERNS IN THE SHELL OF THE COCKLE, *FULVIA MUTICA* FROM KOREA. Do-Hyung Kang¹, Heung-Sik Park², Chris A. Richardson³ and Kwang-Sik Choi¹.

¹School of Applied Marine Science, College of Ocean Science, Cheju National University, 1 Ara 1-Dong Jeju 690-756 Republic of Korea, ²Korea Ocean Research & Development Institute, Ansan P.O. Box 29 425-600 Republic of Korea, ³School of Ocean Sciences, University of Wales, Bangor, Menai Bridge, Gwynedd LL59 5AB, UK.

Growth banding, consisting of a pattern of narrow tidally deposited dark bands and wider light growth increments, were identified in acetate peel replicas of shell section of live collected cockle, *Fulvia mutica* (Bivalvia: Cardiidae) collected subtidally from Jukdo, Korea. The total number of dark growth bands and the inter-band distance (i.e. growth increments) were counted and measured respectively using image-processing software. The age of the cockle was estimated by counting the number of dark bands in the sectioned shell and the prominent dark lines in the umbo region. The oldest cockle determined using these methods was 6.5 years. The width of the growth increments varied from 23.4 μm in a 3rd dark line to 1.2 μm in a 6th dark line in the umbo region of oldest cockle. Each wide light tidal increment was dated and the width of the increment compared with the daily seawater temperature; a positive correlation between increment width and seawater

temperature was observed opening up the possibility of using the tidal increments for environmental reconstruction of shell growth rates.

APPLICATION OF RECENT RED ABALONE *HALIOTIS RUFESCENS* SURVEYS TO MANAGEMENT DECISIONS OUTLINED IN THE CALIFORNIA ABALONE RECOVERY AND MANAGEMENT PLAN. Jerry V. Kashiwada¹ and Jan K. Taniguchi². ¹California Department of Fish and Game, Fort Bragg, CA 95437, ²California Department of Fish and Game, Los Alamitos, CA 90720.

The management section of California's recently adopted Abalone Recovery and Management Plan (ARMP) uses results of fishery independent transect surveys at eight index sites to regulate Total Allowable Catch (TAC). A decision table in the ARMP (Table 1) uses densities in deep water (>8.2 to 19.7 m), densities over all depths, and successful recruitment (>4,500 abalone/hectare in the 100–177 mm size class) to decide whether changes need to be made in the TAC. The TAC is estimated from telephone surveys and returned Abalone Permit Report Cards. Recent surveys in 2003 and 2005 at four of the eight index sites show red abalone densities in the range of the baseline densities established by surveys in 1999 and 2000. Applying the results of the 2003 and 2005 surveys to the ARMP decision table indicates no change is needed in the current TAC. Two-way ANOVA found there was no difference in density between sites and time periods for all depths at two of the sites (Van Damme and Salt Point) which were surveyed in both time periods. Likewise there was no significant difference at deep depths between these two sites and time periods.

COULD *LIMNOPERNA FORTUNEI* BE WORSE THAN *DREISSENA POLYMORPHA*? POTENTIAL SPREAD AND ECOSYSTEM IMPACTS. Alexander Y. Karatayev¹, Dmetrio Boltovskoy², Dianna K. Padilla³ and Lyubov E. Burlakova¹.

¹Stephen F. Austin State University, Department of Biology, Box 13003-SFA Station, Nacogdoches, TX 75962-3003, ²Universidad de Buenos Aires, Argentina, ³Stony Brook University, Stony Brook, NY.

Although taxonomically unrelated, the zebra mussel (*Dreissena polymorpha*) and golden mussel (*Limnoperna fortunei*) have very similar life histories, suggesting that similar vectors are involved in their spread. Both are sessile, byssate bivalves with a planktonic larval stage and high reproductive capacity. Adults of both species attain extremely high densities physically changing the substrate, and because they are such effective suspension feeders they greatly enhance benthic-pelagic coupling and act as powerful ecosystem engineers. We compare environmental limits and ecological impacts of the well studied *D. polymorpha* with the lesser known *L. fortunei* to predict the potential spread and ecosystem impacts of the golden mussels. *Limnoperna fortunei* reaches population densities similar to or higher than *D. polymorpha*. It has comparable

filtering rates and therefore may have similar or even stronger ecosystem impacts. In addition, *L. fortunei* has broader environmental tolerances than *D. polymorpha*, including higher water temperatures, lower pH levels, lower calcium content and water pollution. Therefore, *L. fortunei* may be much more successful than *D. polymorpha* in regions dominated by acidic, soft and contaminated waters. We predict that in the near future *L. fortunei* will colonize the southern and central parts of North America, Southern Europe, Northern Africa, and Australia, as well as expand its distribution in South America and Asia. Although to date *D. polymorpha* is considered the most aggressive freshwater invader, soon many waterbodies that are already affected by *D. polymorpha* may get another, even more aggressive invader.

ENHANCED BLUE CRAB ABUNDANCE ON RESTORED OYSTER REEFS. M. Lisa Kellogg¹, Christopher McIntyre², Kennedy C. Paynter¹ and Kennedy T. Paynter¹. ¹University of Maryland, ²Coastal Carolina University.

In recent years, the goals of oyster reef restoration in Chesapeake Bay have shifted from simply enhancing the oyster fishery to restoring the ecosystem services that were once provided by healthy oyster reefs. Like historical reefs, restored oyster reefs produce topographically-complex reef structures that enhance both the abundance and diversity of the associated macrofaunal community. Restored oyster reefs, therefore, have the potential to provide highly-mobile organisms such as the blue crab, *Callinectes sapidus*, with both an abundant supply of prey and a refuge from predation. To determine whether restored oyster reefs are a preferred habitat for blue crabs, blue crab populations were estimated on restored oyster reefs and adjacent control areas at two restoration sites in the South River: Glebe Bay and Duvall Creek. On each sampling day, one 50-m trotline was laid on the restored reef and another was placed on an adjacent unrestored control area. Alternating between the two lines, each line was sampled 10 times. All crabs caught were retained to avoid recapture of the same individuals. More crabs were caught on the restored reefs than the control sites at both Glebe Bay ($p = 0.004$) and Duvall Creek ($p = 0.037$). Assuming these capture rates represent relative crab abundances, these preliminary findings suggest that blue crab densities may be higher on restored oyster reefs. However, additional studies will be necessary to determine why blue crabs prefer the restored reefs, and whether restored reefs enhance blue crab production.

DEVELOPMENT OF SINGLE NUCLEOTIDE POLYMORPHISMS (SNPS) IN THE PACIFIC OYSTER *CRASSOSTREA GIGAS*. Woo-jin Kim¹, Hyungtaek Jung² and Patrick Gaffney². ¹National Fisheries Research and Development Institute, Busan, South Korea, ²University of Delaware.

Single nucleotide polymorphisms (SNPs) are useful for characterizing population structure, genetic mapping, and as a tool for pedigree monitoring and marker-assisted breeding schemes. Our

objective is to develop SNP markers for the Pacific oyster *Crassostrea gigas*, the most widely cultured bivalve species. Primers were designed based from expressed sequence tags (ESTs) to amplify small fragments (200–400 bp) spanning the 3' end of coding sequence and the 5' end of the 3'UTR. Most (22 of 24) primer pairs successfully amplified PCR products from genomic DNA. Direct sequencing of amplified targets resulted in the identification of 321 candidate SNPs within 22 identified nuclear genes. The observed frequency of SNPs in *C. gigas* was 4.32 per 100 bp: 1.94 in exons, 9.06 in introns, and 4.64 in the 3'UTR. Individuals from an inbred hatchery line showed reduced polymorphism. Oysters from three populations of *C. gigas* (Korea, Hokkaido, Kyushu) and one *C. angulata* population (Portugal) could be differentiated using estimated genetic similarity based on SNP allele-sharing at ten loci. All loci were successfully amplified from *C. angulata*, underscoring its close genetic relationship to *C. gigas*. The majority of identified SNPs differed between the two species, providing multiple independent markers for identification of both species and hybrids, and for marker-assisted introgressive hybridization. Mapping of these loci is in progress. The SNP markers developed in this study will enable researchers to elucidate population structure in the native range of the two species, as well as the characterization of cultured lines.

RELATIONSHIPS AMONG PARASITES AND PATHOLOGIES IN SENTINEL BIVALVES: NOAA STATUS AND TRENDS 'MUSSEL WATCH' PROGRAM. Yungkul Kim and Eric N. Powell, Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Ave., Port Norris, NJ 08349 USA.

NOAA's National Status and Trends 'Mussel Watch' Program includes a comprehensive survey of the histopathology of sentinel bivalves from the East, West, Gulf, and Great Lakes coasts of the United States. We analyzed the data for 1995–1998 to identify relationships between various parasites, various pathologies, and between parasite/pathology pairs with the goal of identifying consistencies and differences in these relationships between sentinel bivalves and between major geographic units of the U.S. coastline. The prevalences of parasite, pathology, and parasite-pathology pairs were significantly correlated more frequently for oysters than for mussels. The number of significant correlations within Gulf-coast oysters exceeded the number within East-coast oysters. Correlations were least frequent among East-coast mussels. The incidence of significant negative correlations in prevalence far exceeded the incidence of significant positive correlations in all species and bay regions. Significant relationships in infection intensity occurred much less frequently than for prevalence. Positive correlations occurred more frequently than they did for prevalence. Both trends reinforce the belief that environmental factors controlling transmission are likely distinctive from those controlling proliferation. Only a few relationships between parasites were com-

mon to more than one sentinel bivalve or more than one coastal region. Not a single common relationship involved a pathology. However, though commonalities were few, consistent trends in prevalence between mussels and oysters and between coastal regions suggest potentially important large-scale trends among some important parasite groups, particularly the gregarines and gut ciliates, gill gregarines and cestodes, prokaryotic inclusions and trematode metacercariae, and *Perkinsus marinus* and the gregarines.

COMPARISONS OF POST-SETTLEMENT SURVIVAL AND GROWTH IN *CRASSOSTREA VIRGINICA* AND *C. ARIAKENSIS* IN RELATION TO TIDAL EMERSION. Peter R. Kingsley-Smith and M. Luckenbach, Virginia Institute of Marine Science.

In many high salinity regions of the mid-Atlantic *C. virginica* is limited to the intertidal zone where it achieves a partial refuge from predation. Persistence in such intertidal habitats necessitates tolerance of both desiccation and extremes of temperature during periods of aerial exposure. Such capabilities in *C. ariakensis* have yet to be determined. The effects of aerial exposure by tidal emersion on comparative survival and growth rates of diploid *C. ariakensis* and diploid *C. virginica* were investigated using oysters set on plastic tiles and grown in a flow-through quarantine system. Four tidal regimes were simulated: 1) *high intertidal* (3.5 hrs emersion), 2) *mid tide* (2 hrs emersion), 3) *low intertidal* (1 hr emersion) and 4) *subtidal* (constant immersion). Vertical ("North-facing" and "South-facing") and horizontal ("Up" and "Down") tile orientation treatments were also incorporated in the experimental design. Tiles were individually photographed on a weekly basis between June and August 2005 and image analysis software was used to gather survival and growth data.

The high intertidal treatment exceeded the physiological tolerances of both species; complete mortality occurred within the first two weeks. In the mid tide and the low intertidal treatments *C. ariakensis* and *C. virginica* exhibited intermediate growth and survival. Growth rates were highest and levels of mortality were lowest in the subtidal treatment. Determination of the tolerance of *C. ariakensis* to aerial exposure will improve our understanding of its potential to colonize intertidal habitats, to compete with native species for resources, and to become a fouling nuisance if introduced.

MEASUREMENT OF SCOPE-FOR-GROWTH IN FRESHWATER MUSSELS AND THE RELEVANCE FOR WATER QUALITY, ECOSYSTEM FUNCTION AND BIOMONITORING. Danielle A. Kreeger, Partnership for the Delaware Estuary, 110 S. Poplar St., Suite 202, Wilmington, DE 19801.

Native freshwater mussels continue to garner increasing attention for their biodiversity plight, ecological value, and usefulness for biomonitoring. Despite the rising chorus, many key aspects of

their basic biology remain poorly studied. Of particular note is the lack of attention to organism-level physiological functions that represent the nexus, or "missing link," essential to relating environmental conditions to population- and species-level fitness, and vice versa. Small spatial and temporal shifts in environmental conditions, food quantity and quality, or animal nutritional demands can elicit significant shifts in organism-level processing rates and fitness, with concomitant effects to the ecosystem where populations remain abundant. Decades of research with marine species have yielded an arsenal of powerful methods to quantify spatial, temporal, intraspecific and interspecific variation in physiological rates and status. And yet, only one physiological rate metric (clearance) and one status metric (condition) have been widely adopted for freshwater mussels, and their meaning has at times been misinterpreted. In this presentation I will briefly review the available "tool kit," describe methods needed to calculate scope-for-growth, and discuss the proper interpretation of these and other physiological metrics as being context specific, rather than absolute. Specifically, I will present case study data for the allometric rates of clearance, defecation, excretion and respiration of species from both the Atlantic and Pacific slopes. When standardized and understood, physiological methods and information will play a pivotal role in monitoring and optimizing the health of captive animals, quantifying the functional importance of mussel populations in nature, and biomonitoring the status of our waterways.

TRANSPARENT EXOPOLYMER PARTICLES (TEP) FROM SUSPENSION FEEDERS AND THEIR EFFECTS ON PARTICLE AGGREGATION. Binglin Li and J. Evan Ward, University of Connecticut, Marine Sciences Building, 1080 Shennecosset Rd., Groton, CT 06340.

Transparent exopolymer particles (TEP) can form from dissolved precursors released by phytoplankton. Recent studies have also demonstrated that benthic suspension feeders, such as bivalves, can contribute significantly to the TEP pool in coastal waters. Whereas TEP from phytoplankton is important for the aggregation of suspended material, the role of TEP from suspension feeders on aggregate formation is unknown. The purpose of this study was to test the hypothesis that organic compounds, including TEP, released from suspension feeders enhance the formation of particle aggregates in coastal waters. In laboratory experiments, TEP was collected from blue mussels (*Mytilus edulis*) and sea vases (*Ciona intestinalis*) using previously established methods. One of two particle types, silica-amino beads or diatomaceous earth (ca. 10 μm), were then added to seawater with and without TEP produced by the animals. Bottles (250 ml) containing suspended particles were placed on a roller table and rolled for 48

hours. Changes in the size distribution of particles in each jar were followed over time by means of an electronic particle counter, and aggregates larger than 100 μm were counted using a rafter cell and microscope. Dissolved and total organic carbon and bacterial concentrations were determined before and after the rolling period. Results indicate that significantly more particle aggregates are produced in seawater containing TEP from suspension-feeding animals than in control water. Aggregation of both particles types was similarly enhanced. Our results suggest that organic material released by suspension-feeders can enhance aggregate formation and hence the deposition of material to the benthos.

VARIANCE IN REPRODUCTIVE SUCCESS OF THE FLAT OYSTER *OSTREA EDULIS* L. ASSESSED BY MICROSATELLITE-BASED PARENTAGE ANALYSES. Delphine Lallias¹, Nicolas Tairs¹, Pierre Boudry¹, François Bonhomme² and Sylvie Lapègue¹. ¹INFREMER—LGP, Station de La Tremblade, La Tremblade, France 17390. ²UMR5171 Ifremer-CNRS—Université Montpellier II, Sète, France.

The European flat oyster (*Ostrea edulis* L.) is a marine bivalve whose natural geographical distribution ranges along the European Atlantic coast from Norway to Morocco, in addition to the Mediterranean and Black Sea. Previous studies of allozymes, microsatellites and mitochondrial differentiation over the whole range concluded that a significant divergence existed between Mediterranean and Atlantic populations, together with an isolation-by-distance pattern. However, the average mitochondrial haplotypic diversity displayed a high among populations variance, reflecting smaller effective population size in some locations. Additionally, a ten-fold quantitative difference was observed in the same study in Fst between the mitochondrial and the nuclear genomes, which could be due to sex biased differential reproductive success between males and females. In order to further document this hypothesis, two experiments were conducted. First, brooding females were sampled in a wild population and the number of males fertilizing a given female estimated. Then, parentage analyses were achieved under experimental conditions: successive mass spawnings were collected from a population of potential genitors kept in hatchery, whose genotypes were known, in order to infer a posteriori the relative contribution of each genitor. Moreover, we aimed to better understand the reproduction dynamics of this species. Several patterns of spawning could be distinguished: unique, successive or extended in time. The different parental contributions and reproductive behaviors observed in these experiments are discussed in the context of the hypothesis of a variance in the reproductive success of males and females and consequences in local and temporal reduced effective population sizes.

TRANSCRIPTOME ANALYSIS OF PACIFIC OYSTER *CRASSOSTREA GIGAS* FAMILIES EXPOSED TO HEAT STRESS. Paul Lang¹, Christopher J. Langdon¹ and Mark D. Camara². ¹Oregon State University, Department of Fisheries and Wildlife, Hatfield Marine Science Center, Newport, OR 97365. ²United States Department of Agriculture, ARS Program, Hatfield Marine Science Center, Newport, OR 97365.

We studied the transcriptome level response of oysters to heat stress using microarrays developed by the Oyster Microarray Consortium to compare gene expression among selectively-bred oyster families that differed in sensitivity to heat stress. Spat ($n = 100$ each per family) of 53 oyster families were exposed to 43°C water for 1 h. We then assessed mortality 2–4 intervals for six d. Survival ranged from 6% to 85% and we classified families with >70% survival as resistant those with 30–70% survival as moderately resistant, and those with <30% survival as sensitive. Animals from the four highest- and the four lowest-surviving families were reared to two years of age and tested again. Survival ranged from 0.03% to 95% for adults. Four of the eight families retained their classification of heat-resistant or heat-sensitive, and the remaining four families were re-classified as moderately heat sensitive.

For transcriptome analysis, we exposed the two resistant families and two susceptible families to a non-lethal heat shock (40°C for 1 h) and collected gill tissue from three animals per family at 1 h, 3 h, 6 h, and 24 h following heat shock. We pooled tissue samples within family for each sampling time and extracted total RNA from each pooled sample. We labeled each RNA sample with a fluorescent dye, and hybridized the sample to a single microarray chip. Fluorescence data was collected using a Scan-Array Express instrument. Genes that underwent coordinated changes in expression level were clustered into groups using multivariate exploratory analysis. The results of these analyses will be discussed.

THE POTENTIAL ROLE OF FRESHWATER MUSSELS IN REDUCING *GIARDIA* AND OTHER HUMAN PATHOGENS IN WATERSHEDS OF THE PACIFIC NORTHWEST. Chris Langdon¹, David Close² and Peggy Bradley³. ¹Hatfield Marine Science Center, Oregon State University, ²Confederated Tribes of the Umatilla Indian Reservation, ³Institute of Simplified Hydroponics.

Freshwater mussels were abundant in rivers of the Pacific Northwest and were an important source of nutrition for many Native Americans in pre-European times. Since then, populations of freshwater mussels have declined. Habitat changes, pollution and declines in salmon (an important upstream transport vector of larval stages) are likely causes. These declines will result in a reduction in the filtering capacity of mussel populations and removal of suspended sediments and organisms, including the human pathogens *Giardia duodenalis* and *Cryptosporidium parvum*.

Laboratory studies showed that adult (91–127 mm shell length) freshwater mussels (*Margaritifera falcata*) filtered mice-derived *Girardia* (*G. muris*) at rates of $0.49 \text{ l h}^{-1} \text{ g}^{-1}$ mussel dry weight. In addition, mussels filtered microalgae [*Schizochytrium* sp.; in the same size range as *G. duodenalis* (2.7–7.1 μm)] at rates of 0.39 to $0.41 \text{ l h}^{-1} \text{ g}^{-1}$ dry weight. The filtering action of mussels could be an important natural mechanism for reducing concentrations of human pathogens in streams and rivers.

IMPROVEMENT IN YIELDS OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS* AFTER TWO GENERATIONS OF SELECTION. Chris Langdon, Ford Evans, Sean Matson, Drew Mosher and Alan Barton. Hatfield Marine Science Center, Oregon State University.

Globally, the Pacific oyster is the most valuable aquaculture species, with a harvest of 4.2 million metric tons valued at \$3.5 billion (FAO Fisheries Statistics 2002). The West Coast is the biggest regional producer of oysters in the U.S. with a wholesale value of \$68 million. In contrast to many other U.S. agricultural commodities, there had been no long-term, funded research program to select and manage Pacific oyster broodstock for enhanced production. In response to this need, the Molluscan Broodstock Program (MBP) was established in 1995 to implement a selective breeding program to improve broodstock and increase commercial production of Pacific oysters on the West Coast, U.S. Since MBP's inception, about 1300 oyster families have been planted and evaluated at commercial grow-out sites from Alaska to California, U.S. Results show that after two generations of selection, the average yield of oyster families derived from selected MBP broodstock is 29% greater than that of families from 'wild' unselected broodstock and 34% greater than that of industry broodstock. Furthermore, the five top-performing families (recommended for commercial hatcheries) from F2 MBP cohorts have an average yield that is 77% greater than that of families from industry broodstock. MBP broodstock are used in commercial hatcheries for large-scale seed production.

A LEAST COST FORMULATED FEED FOR GONAD PRODUCTION OF THE SEA URCHIN *LYTECHINUS VARIEGATUS*. A. L. Lawrence¹, S. A. Watts², M. L. Powell² and J. M. Lawrence³. ¹Texas A&M University System, 1300 Port Street, Port Aransas, Texas 78373, ²University of Alabama, Birmingham, Birmingham, Alabama 35294, ³University of South Florida, Tampa, Florida 33620.

Feeds are critical to successful aquaculture production. Feed usually represent 30% to 50% of the variable cost. Dry pelleted semi-purified feeds have recently been used to produce roe of marketable quality for *Lytechinus variegatus*. Using ingredient and nutrient limits for semi-purified feeds and substituting practical

ingredients for purified ingredients such as whole wheat grain for wheat starch and dehulled, defatted soybean meal (48% protein) for purified isolated soy protein, a commercial urchin feed was formulated using a least cost program. Calculated feed levels for crude protein, soluble carbohydrate, crude fiber, total ash and crude fat were 25%, 34.9%, 2.9%, 19.5%, and 7.5%, respectively, with an ingredient cost of \$609.90/M.T. Protein was the most expensive nutrient with feed costs decreasing to \$557.70 and increasing to \$659.80/M.T. for 15% and 35% protein feed levels, respectively. Marine (e.g. kelp, fish) and lipid (e.g. carotenoid, cholesterol) ingredients represented the largest ingredient costs. Estimating feed mill administrative, amortization, production and margin is approximately \$200/M.T., the selling price for 25% protein commercial urchin feed would be \$809.90/M.T. Using shrimp raceway and feed technology and economic data and data obtained last year by the University of Alabama at Birmingham and Texas A&M System, urchin aquaculture for roe production for human consumption has a larger potential margin than intensive shrimp production in raceways.

SIZE-SPECIFIC SURVIVAL AND FISHING MORTALITY ESTIMATES FOR RED ABALONE, *HALIOTIS RUFESCENS*, USING MARK-RECAPTURE DATA. Robert Leaf^{*1}, Laura Rogers-Bennett² and Peter L. Haaker³. ¹Virginia Tech, ²Bodega Marine Lab and California Department of Fish and Game, ³California Department of Fish and Game.

Estimates of size specific natural and fishing mortality are currently not available for red abalone, *Haliotis rufescens*, in northern California. We examined annual survivorship of three size classes (<100 mm, 100.1 to 178 mm, and >178 mm, the legal fishing limit) of red abalone using capture-mark-recapture data in northern California. We estimate fishing mortality comparing fished and reserve sites in northern California. The number of tagged individuals ($n = 273$ to 2,145), survey occasions ($n = 3$ to 7), and size composition of individuals (41.5 to 227 mm, maximum shell length, MSL) were variable at each site. The annual survival probabilities of the smallest size class (<100 mm MSL) at one reserve site in northern California was $0.52 \text{ y}^{-1} \pm (0.05 \text{ SE})$ and was $0.36 \text{ y}^{-1} \pm (0.07 \text{ SE})$ to $0.51 \text{ y}^{-1} \pm (0.08 \text{ SE})$ in southern California. Annual survival of the mid-size class (100.1 to 178 mm MSL) from four sites at northern California ranged from $0.47 \text{ y}^{-1} \pm (0.05 \text{ SE})$ to $0.71 \text{ y}^{-1} \pm (0.04 \text{ SE})$. The largest size class (>178 mm MSL) had a large range of annual survivorship values of $0.26 \text{ y}^{-1} \pm (0.06 \text{ SE})$ to $0.95 \text{ y}^{-1} \pm (0.08 \text{ SE})$ in fished and reserve sites in northern California. Instantaneous fishing mortality (F) was estimated to be 0.68 to 1.29. This study is an example of how capture-mark-recapture data from fished and reserve sites and the selection of parsimonious models can be used to estimate natural and fishing mortality estimates.

PRELIMINARY VALIDATION OF AGE-AT-LENGTH OF RED ABALONE, *HALIOTIS RUFESCENS*, USING BOMB RADIOCARBON. Robert T. Leaf¹, Allen H. Andrews² and Gregor M. Cailliet². ¹Virginia Tech, ²Moss Landing Marine Laboratories.

Current methods to describe the age-at-length relationship of red abalone (*Haliotis rufescens* Swainson) are insufficient to determine the ages of large individuals because their shell lengths exceed those predicted by model L_{∞} values. We evaluated the utility of analyzing atomic bomb generated radioisotope ^{14}C in shell as a method to validate the age-at-length relationship of *H. rufescens*. Fabens' (1965) method was used to determine von Bertalanffy growth function (VBGF) parameters (L_{∞} 313 mm, $k = 0.051 \text{ y}^{-1}$ (0.042 to 0.059, 95% CI)) based on data from a multi-year, multi-site tag-recapture study. Shell carbonate was sampled at four locations on a single shell (251 mm, maximum shell length (MSL)) with the objective to bracket the rise of the radiocarbon signal, known to occur during ~1957 in the NE Pacific. There was close correspondence to the radiocarbon values of extracted shell carbonate and estimated dates of formation based on VBGF estimates. The 251 mm (MSL) red abalone specimen was predicted to be 27 to 38 years old. This study presents preliminary results from radiocarbon analysis of shell carbonate and demonstrates the utility of validating the age-at-length relationship of red abalone with this method.

SEED QUALITY ASSESSMENT OF *MYTILUS EDULIS* STOCKS IN THE GULF OF ST. LAWRENCE, CANADA. Neil Leblanc¹, Fabrice Pernet¹, Rejean Tremblay², Thomas Landry³ and Jeff Davidson⁴. ¹Coastal Zones Research Institute, ²University of Quebec, ³Fisheries and Oceans, ⁴Atlantic Veterinary College.

Seed supply is a crucial part of any aquaculture operation and the mussel industry in eastern Canada is no exception. This industry relies solely on wild spat collection to furnish seed for its aquaculture operations. High mortality in cultured mussels has periodically been a problem in the Gulf region and this has sometimes been attributed directly to the seed stock that has been used. This has occurred in the absence of a pathological explanation and studies on mussel stocks in the Gulf region have pointed to the genetic composition of mussel populations as a significant factor contributing to large scale mortality events.

The objective of the study was to develop and assess seed quality criteria for *Mytilus edulis*. We have taken mussel seed from six different locations in two provinces in the Gulf region and performed a reciprocal transfer among the seed source sites creating a 6 × 6 (seed × location) field study using a total of 3240 individually tagged mussels. Productivity was measured using the variables growth, survival, and condition index. Explanatory vari-

ables included lipid content and composition, heterozygosity level, microsatellites loci characterization, histology and oxygen consumption.

THE EFFECTS OF ANTI-FOULING TREATMENTS FOR *STYELA CLAVA* ON LONG-LINE CULTURED *MYTILUS EDULIS* IN PRINCE EDWARD ISLAND, CANADA. Neil Leblanc¹, Jeffery Davidson¹, Mary McNiven¹, Thomas Landry² and Rejean Tremblay³. ¹Atlantic Veterinary College, ²Fisheries and Oceans, ³University of Quebec.

Currently, the mussel industry in Prince Edward Island is facing serious production problems associated with an invading species, *Styela clava*, or clubbed tunicate, is an invading species found in Prince Edward Island in the late 1990's. It is a sessile filter feeder, which forms dense colonies on mussel lines causing several serious production problems. In the first few bays found to contain this organism, the mussel farms were overwhelmed by this invader. The objective of this experiment was to determine the effect that acetic acid treatments, used to get rid of the tunicates, has on the mussels being farmed. A field trial was conducted in November 2002 involving ½ inch socked juvenile mussels. The trial involved two acetic acid treatments, a thirty second and two-minute dip in 5% acetic acid. The treated and control socks were then placed systematically on a longline in New London Bay, Prince Edward Island from north to south in the order two-minute acetic acid dip, control, thirty second acetic acid dip. Seven months later, in June 2003, the line was retrieved. Studies in the lab consisted of weighing the entire sock, two-foot sections, measuring 500+ specimens per treatment for length, performing a condition index experiment on thirty specimens of each treatment, and allozyme analysis on fifty individuals per treatment to determine heterozygosity. This experiment indicates that acetic acid can be fatal to mussels but does not cause serious longterm health problems. These factors should be taken into account when devising methods and dosages for the anti-fouling treatments.

MINING EST DATABASE FOR SINGLE-NUCLEOTIDE POLYMORPHISMS IN THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*). Jeong-ho Lee and Ximing Guo. Haskin Shellfish Research Laboratory, Rutgers University.

Single-nucleotide polymorphisms (SNPs) are important resources in genomic analysis, particularly when they are derived from expressed sequence tags (ESTs). SNPs derived from EST are excellent markers for genetic mapping because of their representation of functional genes and potential for high throughput genotyping. SNPs can be developed by re-sequencing or by mining existing sequence databases. The public EST databases represent an enormous but heterogeneous repository of sequences, including many from a broad selection of oyster species and varieties. The significant redundancy within large EST collections makes them an attractive resource for rapid identification of SNPs. At the

present time, only a limited number of SNPs are available in the eastern oyster (*Crassostrea virginica*). In this study, we used a bioinformatics strategy to discover SNPs within an eastern oyster EST database. A collection of >9,000 eastern oyster ESTs was downloaded from GenBank and assembled into 602 contiguous sequences (contigs). The contigs were then visually inspected to identify SNPs with high minor allele frequencies and good flanking sequences. A total of 206 candidate SNPs from 100 genes were identified and characterized. Polymorphism information content for the SNPs ranged from 0.11 to 0.50. They are being validated and mapped in the eastern oyster.

EFFECTS OF THE DINOFLAGELLATE *KARENIA BREVIS* ON LARVAL DEVELOPMENT IN THREE SPECIES OF BIVALVE MOLLUSC FROM FLORIDA. Jay R. Leverone¹, Norman J. Blake² and Sandra E. Shumway³. ¹Mote Marine Laboratory; University of South Florida, ²University of South Florida, ³University of Connecticut, Groton, CT.

The effects of *Karenia brevis* (Wilson clone) on larval survival and development of the bay scallop, *Argopecten irradians*, northern quahog, *Mercenaria mercenaria*, and eastern oyster, *Crassostrea virginica*, were studied in the laboratory. Larvae were exposed to cultures of whole and lysed cells, with mean total brevetoxin concentrations of 53.8 and 68.9 $\mu\text{g} \cdot \text{L}^{-1}$, respectively. Survival of early (3-day-old) larvae was generally over 85% for all shellfish species at *K. brevis* densities of 100 cells $\cdot \text{mL}^{-1}$ or less, and not significantly different between whole and lysed culture. At 1,000 cells $\cdot \text{mL}^{-1}$, survival was significantly less in lysed culture than whole culture for both *M. mercenaria* and *C. virginica*. Survival of late (7-day-old) larvae in all three species was not significantly affected by *K. brevis* densities of 1,000 cells $\cdot \text{mL}^{-1}$ or less. At 5,000 cells $\cdot \text{mL}^{-1}$, however, survival was reduced to 37, 26 and 19% for *A. irradians*, *M. mercenaria* and *C. virginica*, respectively. Development of *C. virginica* and *M. mercenaria* larvae was protracted at *K. brevis* densities of 1,000 cells $\cdot \text{mL}^{-1}$ and greater. These results suggest that blooms of *K. brevis*, and particularly their associated brevetoxins, may have detrimental consequences for Florida's shellfisheries by disrupting critical larval processes. Special attention should be paid to blooms of *K. brevis* where these shellfish naturally occur or where aquaculture and restoration activities are either ongoing or planned.

RESPONSE OF BAY SCALLOP POPULATIONS TO LARVAL RELEASES AND AN UPDATE ON CURRENT RESTORATION ACTIVITIES IN PINE ISLAND SOUND, FL. Jay R. Leverone¹, Stephen P. Geiger², William S. Arnold² and Jaime M. Greenawalt³. ¹Mote Marine Laboratory, University of South Florida, ²Florida Fish and Wildlife Research Institute, ³Sanibel-Captiva Conservation Foundation.

In 2003, we undertook a novel restoration approach to enhancing bay scallop populations in Pine Island Sound, Florida. This approach involved releasing competent, late-stage larvae into con-

tainment booms, which isolated the water column, thereby preventing the larvae from excessive dispersion. Three booms were used for larval releases and an additional boom served as a control (no larvae added). Larval settlement and juvenile recruitment were monitored throughout the following year. Scallop spat recruited to artificial substrates in all three treatments. Juvenile scallops, surveyed in Feb 2004, were found at all treatment locations while being absent from the control. Adult scallops, surveyed in July 2004, were two orders of magnitude greater at the restoration site than the resident scallop population within Pine Island Sound. Adult scallops were again surveyed in June 2005. That year, the entire survey area experienced a 100-fold increase in bay scallops from the previous year. Pine Island Sound had the highest abundance of bay scallops than any other Florida estuary in 2005. These results demonstrate that controlled release of competent larvae is a viable method for ultimately restoring bay scallop populations in Pine Island Sound. This fall, our restoration efforts expanded to South Pine Island Sound, a region that has also experienced reduced scallop densities over the past several decades. We will discuss some of the potential problems associated with restoration success at this location, including freshwater inputs and reduced salinity. We are also conducting or planning larval releases in three other Florida Gulf Coast estuaries (Sarasota Bay, Boca Ciega Bay and St. Andrews Bay) during 2005–2006.

CHARACTERIZATION OF NRAMP IN *PERKINSUS MARINUS* AND *CRASSOSTREA VIRGINICA*. Zhouer Lin¹, José A. F. Robledo¹, Gwendolyn Mullen² and Gerardo R. Vasta¹. ¹COMB, UMBI, University of Maryland, Baltimore, MD 21202, USA, ²Morgan State University Graduate School Science Education.

Nramp (natural resistance-associated macrophage protein) is a divalent cation transporter demonstrated to be a determinant of resistance/susceptibility to intracellular pathogens by preventing pathogens from acquiring divalent metals. Reciprocally, most parasites have developed efficient mechanisms for metal acquisition from their hosts. After characterizing Nramp in the oyster parasite, *Perkinsus marinus* (*PmNramp1*), we identified two additional Nramp species in our ongoing *Perkinsus* genome project (<http://www.tigr.org/tdb/e2k4/pmg/>, Microbial Genome Initiative, NSF). Neither intron boundaries nor intron numbers appear to be conserved: 7, at least 4, and 13 introns in *PmNramp1*, *PmNramp2*, and *PmNramp3*, respectively. *PmNramp1* and *PmNramp2* are more similar between them than with respect to *PmNramp3*, so far *PmNramp1* and *PmNramp3* appear to have a TATA-less promoter and the three *PmNramp* are expressed in *P. marinus* cultured trophozoites. We have found several polymorphic sites in *PmNramp1* and we are assessing their potential contribution(s) as virulence factors in the protozoan-oyster interaction. We are also characterizing *Crassostrea virginica* Nramp (*CvNramp*); *CvNramp* messages were identified in samples from hemocytes, mantle, gill,

muscle, and heart. Functional and immunolocalization studies of PmNramp and CvNramp are underway (Supported by Grant ICB-0321417, NSF).

HYBRIDIZATION BETWEEN TWO GENERA OF CLAMS, *SPISULA SOLIDISSIMA* AND *MULINIA LATERALIS*, AND EARLY GROWTH TRIALS. Scott Lindell, Bethany Walton, Janice Simmons and Steven Roberts. Marine Biological Laboratory, Woods Hole, MA.

The Atlantic surfclam (*Spisula solidissima*) and the coot clam (*Mulinia lateralis*) occupy different habitat niches along the eastern North American seaboard. The Atlantic surfclam supports a multi-million dollar fishery and has been the subject of pilot-scale commercial aquaculture. Among the interesting properties of the coot clam that have made it useful to biologists are its ease of culture, short generation time, and high reproductive rate. Despite their apparent geographic and reproductive isolation we have cross-bred these two species in the lab. Larvae of coot clams and both hybrids (*Spisula* eggs \times *Mulinia* sperm and *Mulinia* eggs \times *Spisula* sperm) metamorphosed at 10 days at 20°C and were then reared on set screens and in sand substrate. Results of the first four months of growth of the hybrids and *M. lateralis* will be presented here. We also present information about genetic markers for distinguishing hybrids from their parents. The results have implications for reassessing the taxonomy of mactrid clam species, and may hold promise for a new aquaculture candidate.

ECONOMIC CONSIDERATIONS REGARDING THE RESTORATION OF CHESAPEAKE BAY OYSTER POPULATIONS USING NATIVE OR NON-NATIVE SPECIES. Douglas Lipton, Tom Murray, and James Kirkley

The stated goal of the Environmental Impact Statement related to *Crassostrea ariakensis* introduction in the Chesapeake Bay is to restore the population to a level that could sustain a fishery equivalent to average landings from 1920–1970. Given the changing market for oysters on both the supply and demand side, it is unlikely that a fishery of this size, about 4.9 million bushels per year, is economically feasible. We suggest that a fishery is more likely sustainable at about 2.6 million bushels. In addition to the commercial oyster fishery there are a variety of other costs and benefits related to a restored oyster population. The benefits of a restored oyster population, given current knowledge, appear to be similar whether they are based on the native *C. virginica* or the introduced *C. ariakensis*. Thus, the major differences between the competing options of allowing or not allowing an introduction of a reproducing population of *C. ariakensis* appears to be a risk-time trade-off. The paper discusses the components of this risk-time trade-off in terms of market and non-market benefits and costs.

DOES *PERKINSUS MARINUS* SECRETE EICOSANOIDS?

Eric D. Lund, Fu-Lin E. Chu and Ellen Harvey. Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Perkinsus marinus, a protozoan parasite of the Eastern oyster, *Crassostrea virginica*, causes high mortalities in its host along the Atlantic and Gulf coasts of North America. Several virulence factors of *P. marinus* have been identified, but the mechanisms whereby *P. marinus* overwhelms the host immune response remain poorly understood. One class of virulence factors that has been identified in several protozoan parasites of mammals is eicosanoids, oxygenated metabolites of fatty acids. Previously we have demonstrated that *P. marinus* synthesizes a wide array of saturated, monounsaturated and polyunsaturated fatty acids, including arachidonic acid, a precursor to several eicosanoids including prostaglandins D₂, E₂ and F_{2 α} . To determine if *P. marinus* produces eicosanoids in vitro meronts were cultured in a defined, lipid-free medium supplemented with cholesterol and screened for eicosanoids. GC/MS analysis of a derivatized extract of 4×10^8 *P. marinus* meront cells revealed a peak with a spectrum similar to that of derivatized prostaglandin D₂ (PG D₂), but no other derivatized eicosanoids were detected. Subsequent enzyme immunoassay (EIA) analyses of medium from *P. marinus* meront cultures ($5\text{--}7 \times 10^5$ cells/ml) confirmed the presence of PG D₂ at concentrations between 40 and 140 pg/ml. These levels are comparable to those reported in the literature for *Trypanosoma* and *Plasmodium* species. The function of PG D₂ secreted by *P. marinus* is not currently known. However, prostaglandins synthesized by protozoan parasites of mammals have been shown to be immunosuppressive. This study was supported by a grant from the Metabolic Biochemistry, MCB Division (MCB-031108), National Science Foundation.

ENERGY AND PROTEIN REQUIREMENTS FOR MAINTENANCE AND GROWTH IN THE SEA URCHIN (*PARACENTROTUS LIVIDUS*). Ingrid Lupatsch, Esther Golombek and Muki Shpigiel. National Center for Mariculture Eilat Israel.

A novel approach to determining the protein and energy requirements in sea urchins is described here quantifying the requirements for energy and protein as the sum of the daily requirements for maintenance and growth. Two growth trials of each 91 and 95 days were performed at average temperatures of 22°C using sea urchins of 6.8 g and 12.4 g, respectively. The digestibility of the formulated diet was determined beforehand to contain 190 mg digestible protein and 14.4 kJ digestible energy per g feed. The requirement of digestible energy and protein for maintenance and growth were determined by feeding *Paracentrotus lividus* increasing levels, starting at zero and going up to apparent maximum feed intake. Total energy and protein gain in the urchins were measured by comparative slaughter technique. Protein content of whole live animals ranged from 3.7% initially up to 6.0% at the maximum feeding level corresponding to a gonadosomatic index (wet/wet) of

3.0 to 25.0 respectively. The relationship between digestible energy intake and energy gain was linear and the resulting slope describes the partial efficiency by the sea urchin for energy deposition. The digestible energy requirement for maintenance was calculated to be 32.8 J/g urchin / day and for digestible protein 0.56 mg/g urchin /day. The partial efficiency of utilization for growth was 0.25 and 0.39 for digestible energy and digestible protein respectively. Using these values together with a suitable growth prediction allow optimization of feeds to contain the proper energy to protein ratio for *P. lividus*.

QUANTIFICATION OF QUAHOG PARASITE UNKNOWN (QPX) IN ENVIRONMENTAL SAMPLES. M. Maille Lyons¹, Steven Roberts², Chris Dungan³, Roxanna Smolowitz² and J. Evan Ward¹. ¹University of Connecticut, 1080 Shennecossett Ave, Groton, CT, ²Marine Biological Laboratory, Woods Hole, MA, ³Maryland Department of Natural Resources.

Quahog Parasite X (QPX) is a pathogen of the bivalve mollusc, *Mercenaria mercenaria*, (northern quahog or hard clam). The objective of this study was to develop and validate a quantitative polymerase chain reaction (qPCR) assay that is sensitive and specific for detection of the QPX parasite in experimental and environmental samples. Unique aspects of this qPCR assay development include quantifying the serial dilutions of QPX cells before DNA extraction to calibrate standard curves to cell counts and the targeting of a novel potassium channel gene for amplification. Sensitivity was evaluated with serial dilutions of cultured cells to determine the lowest concentration of DNA that remained detectable in the presence and absence of potential inhibitory environmental compounds. Based on our results, the qPCR assay can effectively quantify QPX within the range of one to several thousand organisms. Specificity was assessed by testing 29 thraustochytrid-like protist strains isolated from oysters (*Crassostrea virginica*, *Crassostrea ariakensis*), softshell clams (*Mya arenaria*) or quahogs (*M. mercenaria*) from Virginia, Chesapeake Bay, China, or Oregon. This technique will provide a valuable tool for characterizing QPX abundances in coastal environments and for improving QPX disease diagnoses in clams.

EVALUATION OF ARTIFICIAL REEF DESIGN FOR OYSTER HABITAT RESTORATION IN GEORGIA. Justin Manley¹, Randal L. Walker¹, Alan Power¹, Dorset Hurley², Mathew Gilligan³ and Joseph P. Richardson³. ¹University of Georgia Marine Extension Service, 20 Ocean Science Circle, Savannah, GA 31405, ²Sapelo Island National Estuarine Research Reserve, ³Savannah State University.

The eastern oyster, *Crassostrea virginica*, is a common estuarine species along the eastern seaboard of the United States and forms dense intertidal fringing reefs in coastal Georgia. Oyster reef acreage has decreased in Georgia over the last century as a result

of commercial harvesting, rapid coastal development, and disease epidemics (*Perkinsus marinus* and *Haplosporidium nelsoni*). Spat abundance is not the limiting factor (settlement rates up to 204,700 m²); rather it is the availability of cultch. Southeastern estuaries are dominated by muddy substrates with oyster reefs forming the only hard substrate. The insufficient return of shell has been detrimental to sustaining oyster populations. The purpose of this study was to determine an optimal cultch material and design for oyster restoration in this environment. Fresh oyster shell, old washed oyster shell, and whelk shell were separately placed into crab traps and plastic mesh bags. Spat collection sticks (PVC tubes embedded with calcium carbonate chips) were arranged in densities of 81 m² and 25 m². Treatments were placed in the Duplin River, Sapelo Island in April 2004. Oyster reef acreage in this area decreased from 8.9 ha in 1891 to 4.3 ha by 2000. Mean annual oyster growth and mortality rates were assessed for each treatment after a one-year period. The collection sticks in the 81 m² treatment performed best (mean annual growth rate: 77.09 mm/year, mortality: 3.467 ± 1.423 %). Structures with higher vertical placement reduce complications associated with high siltation rates and may provide greater surface area for larval attachment.

AGE-SPECIFIC MORTALITY RATES AND CAUSES OF MORTALITY IN NATURAL OYSTER, *CRASSOSTREA VIRGINICA*, POPULATIONS. Roger Mann, Melissa Southworth, Juliana M. Harding and Ryan Carnegie. Virginia Institute of Marine Science.

There are very few estimates of natural mortality rates in natural populations of oysters, *Crassostrea virginica*, (as opposed to abundant estimates from culture and tray type experiments). We offer two methods to estimate natural mortality rates over extended periods and multiple reefs systems for populations in the James River, VA under varying disease challenges. We convert size specific live and box data to age specific demographics, and then generate estimates of age specific mortality from either box ratio (#box / (#box + #live)) or inverse survivor ratios (Live(t) – Live(t + 1)/Live(t)). These are presented and compared with respect to oyster population density, prevalence and intensity data for *Perkinsus marinus*, and river flow data as a surrogate for salinity.

YOU CANNOT GET THERE FROM HERE, CAN YOU? AN EXAMINATION OF THE TIME COURSE AND IMPACT OF OYSTER RESTORATION IN CHESAPEAKE BAY. Roger Mann, Juliana M. Harding and Melissa Southworth. Virginia Institute of Marine Science.

While restoration of the oyster resource of the Chesapeake Bay is supported by extensive research and "on the ground" efforts there has been a reluctance to estimate a realistic time course for achieving both restoration goals and eventual magnitude of impacts on ecological processes, water quality and support of com-

mercial fisheries (noting that these may not be equivalent). Fundamental aspects of oyster biology dictate that such estimates will have similar limitations no matter what species (singular or plural, native or non-native) is considered. We describe the current state of knowledge of stock-recruit relationships, annual replacement ratios, growth rates, age-specific mortality rates in relation to density and disease pressure, and available habitat to provide upper and lower estimates of time to stable terminal carrying capacity (with implications for ecological services and water quality) and potential harvest for commercial purposes.

CONDITION INDICES OF THE EASTERN OYSTER AND REEF CHARACTERIZATION AS RELATED TO WATER QUALITY IN THREE TIDAL CREEKS. Anne L. Markwith, Martin H. Posey and Troy D. Alphin. UNC-Wilmington. Center for Marine Science, 5600 Marvin K. Moss Lane, Wilmington, NC 28409.

The eastern oyster (*Crassostrea virginica*) is an ecologically and commercially important species, providing a series of ecosystem functions (erosion control, filtration, habitat nutrient cycling). This study focuses on the dynamic interaction between oysters and water quality. Through filtration and increased sedimentation oysters have been shown to reduce particulate load in the water column. However, oyster condition and health are also closely linked to water quality conditions, especially total suspended solids (TSS) and sedimentation rates. We expect to see a correlation between the general background water quality, general oyster reef characteristics (density, percent cover, size demography, and rugosity) and measures of oyster condition, such as soft tissue dry weight, volume, and shell characteristics. Data was collected during two sampling periods in three tidal creeks in southeast North Carolina that vary in background water quality characteristics. Sampling occurred during summer (July/August) 2005 and during winter (December 2005/January 2006). All sampling was conducted in the middle section of the creeks, where tidal regime and salinity were similar among sites. Condition index was performed on fifteen randomly selected oysters in two different size ranges per creek using Hopkins' formula: $C.I. = (\text{weight of dry tissue})(100)/(\text{internal shell volume})$. Water quality data and information on watershed development was provided by a long term monitoring project. It was hypothesized that the healthier oysters would be found in the creeks with the historically better water quality levels. Preliminary analysis of the data from the creeks however does not support the hypothesis.

CONDITION INDEX OF SURFCLAMS (*SPISULA SOLIDISSIMA*) IN THE MID-ATLANTIC BIGHT. Rebecca J. Marzec, Yungkul Kim and Eric N. Powell. Haskin Shellfish Research Laboratory, Rutgers University.

Scientists from the Haskin Shellfish Research Laboratory and National Marine Fisheries Service-Northeast Fisheries Science Center conducted a survey of surf clam (*Spisula solidissima*)

stocks in an area from northern New Jersey to southern Virginia during June and July of 2004 in order to evaluate the progress of mortality, apparently related to warming of the Mid-Atlantic Bight. One component of the survey was the measurement of condition index at 104 locations from Delmarva to Long Island. The program followed a pilot study in 2002 that suggested that surf clam mortality off Delmarva was likely caused by warmer temperatures decreasing feeding and subsequently leading to starvation. All sampling was conducted aboard the *F/V Lisa Kim*, a commercial clammer. Condition index was highest inshore, with the exception of a few of the most inshore stations, and lowest at the offshore edge of the clam's range. An estimate of meat weight for a standard 120-mm clam, from site-specific length-weight regressions, revealed that the animals near the center of the inshore-offshore distribution had a greater weight for a given length than those living at the edges of the clam's range, probably due to the influence of temperature on feeding and growth. Low condition in the extreme inshore locations suggests that warmer temperatures continue to negatively affect surf clam nutrition and indicate the continued susceptibility of clams along the southern and inshore boundary to warming in the Mid-Atlantic Bight.

FOULING CONTROL FOR OFF-BOTTOM OYSTER CULTURE USING THE ADJUSTABLE LONGLINE SYSTEM. Vanessa Maxwell and John Supan. Louisiana Sea Grant Development Program, Sea Grant Bldg., Louisiana State University, Baton Rouge, LA 70803.

The Eastern oyster, *Crassostrea virginica*, is an important commercial species in Louisiana. The production of oysters from Louisiana has decreased due to predation, habitat destruction, disease, and the moratorium on leases. Off-bottom culture may be a feasible alternative to increase production, but fouling organisms, such as barnacles and bryozoans, can obstruct mesh openings, reducing growth and survival, and increasing maintenance. The Adjustable Longline System (ALS), commercially used in Australia, allows the oysters to be held at various depths to control culture conditions. This study used the ALS to determine a method of controlling biofouling by measuring 1) growth, 2) survival, and 3) fouling. At the Sea Grant Grand Isle Oyster Hatchery, the ALS was used to test 4 different treatments: a) weekly aerial drying; b) a monthly brine dip; c) daily exposure at low tide; and, d) a no treatment control. Shell height was measured monthly. Fouling was measured monthly by counting organisms on ceramic tiles held on longline cable alongside oyster bags. Total fouling on the oysters was measured by volume at harvest. Oysters reached the legal market size of 76 mm using the ALS within 12 months. Weekly aerial drying had less fouling than either the control or brine dip treatments. The low-tide treatment had the least fouling, but the slowest growth rate. The efficient treatment was weekly aerial drying.

DERMO DISEASE IN STANDARD AND DISEASE-TOLERANT STRAINS OF THE OYSTER (*CRASSOSTREA VIRGINICA*) IN THE PATUXENT RIVER, MD. Carol B. McCollough¹, Christopher F. Dungan¹ and George R. Abbe².

¹Maryland DNR, Fisheries Service, Cooperative Oxford Laboratory, 904 S. Morris Street, Oxford, MD 21654, ²Morgan State University, St. Leonard, MD 20685.

Disease-tolerant strains of the eastern oyster may be of value in population restoration efforts if they outperform the standard strain in survival and growth. Dermo disease measures in two disease-tolerant strains, DEBY and CROSBreed, were compared to those in standard oysters deployed along a salinity gradient in the Patuxent River. In September 2003 tolerant strains were deployed at a size of 3–4 mm; standards were deployed at 16 mm. Whole body burden dermo disease assays were conducted monthly from the time of deployment. Salinities were depressed in 2003 due to above average freshwater inflows. During 2004 and 2005, flows in the Patuxent River returned to normal ranges. *Perkinsus* sp. infections were detected in all strains at all sites during 2004. Typical seasonal patterns in prevalence developed during both 2004 and 2005. Mean sample body burdens from all strains rarely exceeded 30 parasites/gm tissue wet weight, and were typically less than one, except at the downriver site in September 2005 where body burdens in standards and DEBYs reached and exceeded 10² parasites/g. DEBYs exhibited delayed or depressed prevalence peaks compared to CROSBreeds and standards at all sites during the second year; however, prevalences in this strain were not consistently lower than both the others, except at the mid-river site. At this time, strong differences in disease progression between strains are not apparent, but may develop during the third year as these experimental oysters endure further disease pressure as they grow to market size.

RESEARCH PROGRESS ON WHITE ABALONE (*HALIOTIS SORENSENI*). Thomas B. McCormick, Channel Islands Marine Resource Institute.

White abalone (*Haliotis sorenseni*), a large gastropod mollusc in the family *Haliotidae*, was once found in rocky subtidal ocean waters off the west coast of North America from Point Conception in California, south to Punta Abreojos, Baja California, Mexico. Long recruitment intervals, site fidelity, fishing, poaching, disease, and habitat change have contributed to its decline. Surveys of historic habitat in the 1990s indicated that population densities had dropped to less than 0.1% of the estimated pre-exploitation population size. A status review led to a 2001 listing of the white abalone as the first endangered marine invertebrate under the Endangered Species Act of 1976 (66 FR 29053). A cooperative program of research is now providing information many aspects of white abalone biology. Large-scale cultivation of hatchery-raised

white abalone is providing an opportunity to study all life stages of this invertebrate. This presentation will provide a summary of research on age at first sexual maturation, optimal cultivation temperature, density, and diet. Behavioral studies suggest that white abalone are capable of rafting on macroalgae, and may have far greater dispersal capabilities than previously thought.

USE OF A BIOENERGETICS MODEL TO INVESTIGATE THE HABITAT USE AND BEHAVIOR OF A NONINDIGENOUS CRAB, *CARCINUS MAENAS*. P. Sean McDonald¹, Kirstin K. Holsman¹, David A. Beauchamp¹, Brett R. Dumbauld² and David A. Armstrong¹. ¹University of Washington, SAFS, ²USDA, Agricultural Research Service.

We developed an individual-based bioenergetics model to investigate habitat use and migration behavior of non-indigenous European green crab (*Carcinus maenas*) in Willapa Bay, Washington, USA. The model was parameterized using existing studies and applied to four scenarios of habitat use and behavior during a 214-day simulation period (April–October), including crabs occupying (1) sublittoral habitat, (2) sublittoral habitat but undertaking intertidal migrations (3) mid-littoral habitat, and (4) high littoral habitat. Monthly trapping was done along an intertidal gradient to determine the distribution of crabs for the same time interval as the simulation period, and we compared model results to the observed pattern. Model estimates suggest no intrinsic energetic incentive for crabs to occupy littoral habitats since metabolic costs were ~6% higher for these individuals than their sublittoral counterparts. Crabs in the littoral simulations were also less efficient at converting consumed energy into growth than sublittoral crabs, yet trapping revealed abundant *C. maenas* in mid-littoral habitats of Willapa Bay and no evidence of resident sublittoral populations. The discrepancy intimates the significance of interspecific interactions that are not incorporated into the model but nonetheless increase metabolic demand. Agonistic encounters with native Dungeness crabs (*Cancer magister*) may be chief among these added costs, and *C. maenas* may largely avoid interactions by remaining in littoral habitats neglected by native crabs. We suggest that *C. maenas* in Willapa Bay occupy tidal elevations that minimize encounters, and thus metabolic costs, while simultaneously maximizing submersion time and foraging opportunities.

DISTRIBUTION AND QUANTIFICATION OF MULTIXENOBIOTIC RESISTANCE PROTEINS IN THE SEA URCHIN, *LYTECHINUS ANAMESUS*. Nature A. McGinn and Gary N. Cherr. University of California-Davis, Bodega Marine Laboratory, P.O. Box 247, Bodega Bay, CA 94923.

Multixenobiotic resistance (MXR) is an efflux mechanism that uses transport proteins to remove foreign chemicals and waste products from cells. A taxonomically diverse group of marine

organisms express MXR transport proteins and in many larval forms, MXR appears to be a first line of defense against natural toxins and contaminants. Research has shown that marine species express transport proteins similar to mammalian P-glycoprotein (P-gp) and multi-drug resistance-associated proteins (MRPs). MXR proteins are found in molluscan gills where MXR also appears to play a protective role. However, few studies have examined other adult tissues in marine species for expression of MXR proteins. In mammals, homologous multidrug resistance (MDR) proteins occur in tissues with important protective functions including the blood brain barrier and placenta. In this study, we are using the sea urchin, *Lytechinus anamesus*, to investigate the expression and potential function of MXR transport proteins in an adult model marine organism. Preliminary Western blot analysis with a monoclonal antibody indicates expression of P-gp in adult sea urchin tissues including gonads and coelomocytes. We are surveying adult tissues including gonads, gut, tube feet, and coelomocytes as well as major developmental stages for expression of P-gp and MRPs. Study of the larval stages will help elucidate potential transitions in expression and function of the MXR proteins from developing to adult sea urchins. Results from Western blot analysis and immunohistochemistry with custom sea urchin antibodies will be presented. Protein expression data can serve as a baseline for future toxicological research with sea urchins.

THE EFFECTS OF AMMONIA ON THE DEVELOPMENT, SURVIVAL AND METAMORPHIC SUCCESS OF *STROMBUS GIGAS* VELIGERS. Melissa McIntyre¹, Megan Davis² and Amber Shawl². ¹Florida Institute of Technology, Melbourne, FL. ²Harbor Branch Oceanographic Institution, Ft. Pierce, FL.

The Florida Keys queen conch population was a vital fishery, but heavy fishing pressure forced the closure of the commercial fishery in 1976. Since the closure, the recovery of the population has been minimal due to low recruitment of veligers. The queen conch larval stage lasts two to six weeks and during this time veliger survival may be affected by contaminants. Ammonia enters the water through sewage leaching and agricultural runoff. Ammonia is toxic to coral planulae, but toxicity of NH_3 to queen conch larvae has not been established. This study examined the effects of NH_3 on new hatch, five days old, 10 days old, and competent veligers. The treatments tested were artificial seawater; natural seawater; and 1, 10, 100 and 1000 μM of ammonia. Development, mortality and an LC_{50} was determined for each larval stage. Newly hatched veligers exposed to ammonia had a 15–30% increase in mortality over the control after 96 hours. Five day old veligers had 100% mortality in the NH_3 treatments at 96 hours and an LC_{50} of 0.8 μM . Ten day old and competent veligers were robust and able to withstand exposure to levels below 1000 μM .

with LC_{50} 's of 429 and 576 μM , respectively. Metamorphosis was observed in all treatments, excluding 1000 μM ; with natural seawater having the greatest metamorphic success. This study reveals that exposure to NH_3 can compromise the development, survival, and metamorphic success of *Strombus gigas*. The findings of this study will assist in understanding the role ammonia has on recruitment of veligers in the Florida Keys.

COMPARISON OF *CRASSOSTREA ARIAKENSIS* AND *C. VIRGINICA* IN THE DISCHARGE AREA OF A NUCLEAR POWER PLANT IN CENTRAL CHESAPEAKE BAY. Richard I. McLean¹ and George R. Abbe². ¹Maryland Department of Natural Resources. ²Morgan State University.

The potential for introduction of the non-native *Crassostrea ariakensis* into Chesapeake Bay prompted a five month comparison study with *C. virginica* conducted near the Calvert Cliffs Nuclear Power Plant in Maryland, with the primary goal being a comparison of uptake rates of radionuclides released by the plant. The study began with approximately 200 market size triploid *C. ariakensis* (1-yr old) and 200 diploid *C. virginica* (3-yr old) held in secure stainless steel cages 0.5 m off bottom. Half were deployed from July to September 2004, and half from July to December. Although quantities of radionuclides released by the CCNPP were insufficient to yield detectable concentrations in either species, other data were obtained. From July to December, *C. ariakensis* increased its initial shell length by nearly 20% compared to 9% for *C. virginica*. Although mean shell sizes of both species were similar, meat weights and condition indices for *C. ariakensis* were significantly greater ($p < 0.001$) than for *C. virginica*. *C. ariakensis* had lower overall mortality even though nine were lost to blue crab predation during the first exposure period. After five months of exposure, prevalence of Dermo disease in *C. virginica* was 65% with a relative intensity of 1.50 on a 0–7 scale; *C. ariakensis* showed no sign of infection. Although the non-native *C. ariakensis* may have much to offer with high meat yield and disease resistance, rapid growth of triploids results in very thin shells, which may make them more susceptible to blue crab predation than the thicker-shelled *C. virginica*.

GENOMIC ANALYSIS OF GROWTH IN LARVAE OF *CRASSOSTREA GIGAS*. Eli Meyer, Dennis Hedgecock and Donal T. Manahan. University of Southern California, Los Angeles, CA.

Molecular biological analysis has provided important insights into the processes of animal development. However, data on the molecular biological bases of growth are more scant. In particular, the molecular biological bases of hybrid vigor have long remained unresolved despite nearly a century of research and enormous

economic importance. We approached this question by comparing global gene expression patterns in slow- and fast-growing larval families of the Pacific oyster, *Crassostrea gigas*. These different families of larvae were produced through factorial crosses between inbred lines. A total of 4.5 million cDNAs were cloned from 6-day-old larvae and analyzed by "Massively Parallel Signature Sequencing" (Solexa, Inc.). This analysis resulted in quantitative expression profiles and partial sequence data for each of 52,825 unique cDNAs present. Of these, a small subset of 188 genes was found to be differentially expressed in fast-growing hybrid larvae. By comparison with GenBank, 51 of these cloned genes showed significant similarity with DNA sequences for which a function is known; 23 of which represent ribosomal proteins. We found that 40% of these ribosomal proteins were up-regulated and the other 60% down-regulated in fast-growing larvae. These data demonstrate the feasibility of functional genomic approaches and reveal that regulation of protein synthesis machinery is involved in the molecular mechanisms responsible for hybrid vigor. This approach has resulted in the generation of a set of gene probes and possible "markers" that will likely prove useful as early predictors of rapid growth potential in oysters.

THE USE OF MOLECULAR MARKERS TO ASSESS NATIVE OYSTER RESTORATION EFFORTS. Coren A. Milbury and Patrick M. Gaffney, University of Delaware, College of Marine Studies, Lewes, DE 19958.

Restoration efforts are becoming essential in managing many of our ecological resources. Monitoring the efficacy of these programs is essential for evaluating their cost-effectiveness and testing alternative restoration techniques. A majority of oyster restoration efforts use hatchery-produced strains derived from a native stock; however, identifying seed derived from the native population is difficult and requires a high degree of specificity and accuracy. Recent advances in genetic techniques provide high-throughput cost-effective methods for discriminating outplanted seed and their progeny from natives. Our approach is based on shifts in mitochondrial haplotype frequencies occurring during the course of hatchery propagation. Typical natural populations of oysters possess a single major haplotype and an abundance of rare haplotypes. As a result of population bottlenecks during propagation, hatchery seed will often exhibit elevated frequencies of one or more haplotypes that are rare in the source population, allowing discrimination between hatchery seed and natives. Using high-throughput screening techniques, we have identified mitochondrial single nucleotide polymorphisms (mtSNPs) that distinguish hatchery seed planted in the Chesapeake Bay. These markers will be used to determine if outplanted oysters survived and contributed to local recruitment. Even when enhancement stocks are derived from local broodstocks, high-throughput molecular genotyping techniques can allow effective monitoring of enhancement efforts.

DIGESTIVE ENZYME ACTIVITY OVER ONTOGENY IN BAY SCALLOPS, *ARGOPECTEN IRRADIANS*, AND SEA SCALLOPS, *PLACOPECTEN MAGELLANICUS*. Lisa M. Milke, V. Monica Bricelj and Neil W. Ross, National Research Council, Institute for Marine Biosciences, 1411 Oxford St., Halifax, NS, B3H 321 Canada.

Although stage- and species-specific differences in dietary requirements have been demonstrated for bivalves, the mechanisms responsible for differential diet performance remain largely unexplained. While biochemical composition is central to assessing the nutritional value of a diet, an animal's digestive and assimilation capacity are equally important. Digestive capacity of sea and bay scallops may differ 1) over ontogeny associated with morphological changes, and 2) between species, resulting from adaptation to different environments and food supply. To address this, scallop postlarvae [initial shell height (SH) ~250 µm] were reared on a mixed algal diet consisting of one diatom and one flagellate until 4–5 mm SH, and were sampled at intervals coinciding with major morphological changes. Colorimetric assays were conducted to measure the specific activity of carbohydrases (laminarinase, cellulase and alpha-amylase), proteases (azocasein and cathepsin B) and lipase (esterase) in scallop tissues. While preliminary results show no pattern in protease or lipase activity either between species or over development, clear differences in carbohydrase activities were observed. Sea scallops exhibited higher laminarinase activity, but lower levels of alpha-amylase and cellulase than bay scallops, with the most pronounced changes in enzymatic activity occurring prior to attaining ~1.2 mm SH. However, laminarinase activity was significantly higher than activities of either alpha-amylase or cellulase in both scallop species. Our findings have implications for developing targeted diets for commercial hatcheries and increasing our understanding of bivalve-seston interactions in the field.

NATIVE FLORIDA CRUSTACEAN PREDATORS' PREFERENCES REGARDING THE NON-INDIGENOUS GREEN MUSSEL, *PERNA VIRIDIS*. Emily Mitchem¹, Jonathan S. Fajans² and Shirley M. Baker¹. ¹University of Florida, ²Florida Institute of Oceanography.

The green mussel, *Perna viridis*, a native of the Indo-Pacific, was first reported in Tampa Bay in 1999 (Benson et al. 2001; Ingrao et al. 2001). In order to gain a better view of what this invasion might mean for Florida's waters and its native species, this experiment posed the following two-fold question: (1) Will native crustacean predators prey on *P. viridis*? and (2) Will these predators prefer native bivalves over *P. viridis*? Due to the high commercial value of *Panulirus argus*, the Caribbean spiny lobster, and *Callinectes sapidus*, the blue crab, these crustaceans made suitable predator subjects. The eastern oyster, *Crassostrea virginica*, and hard clam, *Mercenaria mercenaria*, were chosen as competing prey because these bivalves are commercially impor-

tant within Florida. Crustaceans and bivalves were placed in a recirculating system with eight 624 liter tanks. Filtration systems included a protein skimmer and fluidized bed, wet-dry filter, and ultraviolet sterilization. Trials ran for fourteen days. *P. argus*, consumed one *C. virginica*, and seventeen *M. mercenaria*. *C. sapidus*, consumed fifteen *P. viridis*, seven *C. virginica*, and seven *M. mercenaria*. A one-way analysis of variance was used to analyze data. A p-value less than 0.05 was considered statistically significant. For the *P. argus* experiment, $p = 0.0219$, showing that *P. argus* data were significant. After this, a Tukey Test was performed. *C. sapidus* data were not statistically significant because $p = 0.2067$, although *C. sapidus* consumed twice as many *P. viridis* than either *M. mercenaria* or *C. virginica*.

MULTIPLE AXES OF VARIATION IN NATURAL POPULATIONS: A COLLISION OF MORPHOLOGY, GENETICS, AND TAXONOMY. Karen E. Mock¹, Jer Pin Chong¹, Jayne Brim-Box² and Jeanette Howard². ¹Utah State University, ²Confederated Tribes of the Umatilla Indian Reservation.

Appropriate classification of taxa is essential for the effective research and management of natural populations. This task is difficult, however, because variation in natural populations occurs along several different, and often incongruent, axes. The difficulty is confounded by disagreement among taxonomists regarding appropriate species definitions. Using a recent example of genetic differentiation among *Anodonta* populations in the Columbia River basin, these issues will be explored as they apply to freshwater mussels.

SABELLID POLYCHAETE INFESTATIONS OF FARMED CALIFORNIA ABALONE. James D. Moore¹, Christy I. Juhasz² and Thea T. Robbins¹. ¹California Department of Fish and Game, P.O. Box 247, Bodega Bay, CA 94923, ²UC Davis, Bodega Marine Laboratory.

The South African sabellid polychaete, *Terebrasabella heteromacinata*, lives in shells of abalone. Accidentally introduced to California during the 1980s, it was spread via abalone shipments to abalone culture and display facilities throughout the state. Eradication efforts have been largely successful although concern remains about whether it has become established in intertidal gastropod populations adjacent to previously-infested facilities. We found that sabellid transmission can occur among native turban snails *Tegula funebris*, corroborating the potential risk of sabellid infestations in native, non-haliotid gastropod populations. Nevertheless, a state-wide survey of turban snails and limpets at 21 exposed or potentially exposed locations found no sabellids, suggesting that the pest has not become established in California. Freshwater treatment is commonly used to sanitize holding units,

hands and equipment at farms and display facilities, but the amount of freshwater required to kill sabellids and their larvae was not well defined. We found that sabellid transmission occurred from infested abalone shells that had been immersed in freshwater for up to eight hours. Additionally, motile sabellid larvae survived up to 32 seconds of immersion in freshwater. We produced an informational video to provide facility staff with recommended practices to achieve eradication and minimize chances of reinfestation. Supported in part by the University of California Integrated Pest Management Program and the Marine Region, California Department of Fish and Game.

COMPARISON OF BACTERIA UPTAKE AND DEPURATION BETWEEN *CRASSOSTREA ARIAKENSIS* AND *CRASSOSTREA VIRGINICA*. James A. Morris Jr.¹, Tanya J. Bean², Rachel T. Noble³ and Patricia K. Fowler². ¹Center for Coastal Fisheries and Habitat Research, National Centers for Coastal Ocean Science, NOAA, Beaufort, NC 28516, ²North Carolina Department of Environment and Natural Resources, Division of Environmental Health Shellfish Sanitation and Recreational Water Quality Section, Morehead City, NC 28557, ³University of North Carolina, Institute of Marine Sciences, Morehead City, NC 28557.

Considerations to introduce the Suminoe, or Asian oyster, *Crassostrea ariakensis*, along the East Coast have raised many questions regarding ecology, economics, and human health. To date, research has focused primarily on the ecological and socioeconomic implications of this initiative, yet few studies have assessed its potential impact on public health. Our work compares the rates of bioaccumulation and depuration of indicator organisms (such as *E. coli*) and *Vibrio* sp. between *C. virginica* and *C. ariakensis* in the laboratory. Preliminary results suggest that the rates of bioaccumulation of *E. coli* in *C. ariakensis* were significantly lower than those for *C. virginica* and that depuration was variable between the two species. This research provides coastal managers with insight into *C. ariakensis* response to bacteria, an important consideration for determining appropriate management strategies for this species. Further field-based studies will be necessary to elucidate the mechanisms responsible for the differences in rates of bioaccumulation and depuration.

SEANEST—A COMMERCIAL SYSTEM FOR LARGE SCALE CULTURE OF BENTHIC SPECIES. Vidar Mortensen, Praktisk Teknologi AS, Norway.

Sea based culture of benthic invertebrates is very labour intensive. This is especially true for species like sea urchin, which require frequent feeding. In addition, traditional equipment like oyster trays fails to accommodate the biological demands of sea

urchins. The SeaNest system has been developed to solve these problems, and to provide the farmer with a modern workplace. Time consuming physical labour is avoided through automatic handling of the holding boxes, and the operator has an ergonomically good position while running the system. The system is designed to meet the biological requirements of sea urchins, with respect to surface area, water exchange, waste removal and short time of air exposure. Further developments towards automatic feeding, cleaning and tracking of holding boxes will provide additional benefits for the farmer. The systems main concepts and technical features will be presented. Prototypes of the system are in use at a commercial sea urchin farm in Norway. The experiences from this farm will be discussed both with regards to sea urchin farming in general, and the function of the SeaNest system in particular. (The SeaNest system is patented, with further patents pending).

OBSERVATIONS OF ASIAN *PERKINSUS* SPECIES AND *PERKINSUS MARINUS* IN THE SUMINOE OYSTER, *CRASSOSTREA ARIAKENSIS*. Jessica A. Moss and Kimberly S. Reece. VIMS, The College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062.

The decline of *Crassostrea virginica* populations has led to an interest in using the non-native oyster species, *Crassostrea ariakensis*, for aquaculture development, fishery resource enhancement and habitat restoration in the Chesapeake Bay region. Previous field studies comparing the performance of *C. ariakensis* and *C. virginica* in the region suggested that the non-native oyster was substantially more tolerant of the endemic protozoan parasite, *Perkinsus marinus*. We conducted a disease survey of *C. ariakensis* in China, Japan and Korea using molecular diagnostics. PCR-based assays revealed two *Perkinsus* species in Asian Suminoe oyster populations that currently are not found in US waters; *Perkinsus olseni* and, based on DNA sequence data, an undescribed *Perkinsus* species. We will report on progress towards molecular characterization of this undescribed *Perkinsus* species. Quarantine protocols for *C. ariakensis* brought to the US from Asia should limit introduction of exotic pathogens, however, it is important to understand the impact that Asian *C. ariakensis* pathogens could have on local bivalve species in case of accidental introduction via the host or through an indirect source such as ballast water, in which case the non-native oyster could act as a pathogen reservoir. We will report results of challenge experiments being conducted with Asian *C. ariakensis* pathogens to examine the impacts on the local Chesapeake Bay bivalve species, *C. virginica* and *Mercenaria mercenaria*, as well as on *C. ariakensis*. During these experiments, we unexpectedly observed the acquisition of moderate and heavy intensity infections of *P. marinus* in *C. ariakensis* oysters being maintained in the laboratory.

GENOMIC EVIDENCE FOR DIVERGENT SELECTION IN EASTERN OYSTER POPULATIONS ACROSS AN ECOTONE. Maria Murray and Matthew P. Hare, University of Maryland.

The eastern oyster, *Crassostrea virginica*, is broadly distributed along the western North Atlantic coastline. Inside this range, a steep latitudinal temperature gradient and a transition in species composition from temperate to subtropical communities generate an ecotone along eastern Florida. Despite evidence for homogenizing gene flow within large continental regions, presumably mediated by a three-week planktonic larval stage, oyster populations display a sharp genetic cline in eastern Florida. We are interested in discovering the abiotic and biotic mechanisms by which a high gene flow species maintains genetic diversity along the ecotone. Population genomics approaches offer effective ways to statistically test for genetic evidence of divergent selection in this non-model species. We report genomic evidence for the role of selection across the ecotone using 215 amplified fragment length polymorphism loci sampled from two populations experiencing the environmental extremes. Simulations of neutral population divergence provided a statistical framework for testing whether differentiation at some loci is greater than expected by genetic drift. For a small portion (2–7%) of loci, allele frequency differentiation was high enough across the ecotone to reject the neutral drift model ($p < 0.01$). Corroborating this inference with additional population sampling, several of the nonneutral AFLP loci show clinal variation concordant with previously described loci. Also, one AFLP locus was converted to a codominant marker and still shows a significantly nonneutral pattern of differentiation. Thus, we infer that divergent selection along the Atlantic Florida ecotone helps maintain genetic differences between oyster populations in the Atlantic and Gulf of Mexico.

EASTERN OYSTER AND HARD CLAM CULTURE FOR THE REDUCTION OF RAS EFFLUENT NUTRIENT COMPOSITION. Amanda Myers, Wade Watanabe and Ami E. Wilbur, University of North Carolina, Wilmington, 7205 Wrightsville Ave., Wilmington, NC 28403.

Closed recirculating aquaculture systems (RAS) are a technological innovation that reduces the amount of water needed for culture by treating and reusing >90% of the total water volume daily. Such systems consequently produce substantially smaller volumes of effluent, but this smaller volume is substantially more enriched in nutrients than effluent from flow-through or open systems. For RAS to emerge as a viable culture strategy, an economical and efficient method must be developed to reduce effluent nutrients concentrations before this effluent is discharged. As part of a larger project evaluating biofilter effects on RAS effluent nutrient composition, this study focused on the effect of bivalve

culture on the composition of effluent from a southern flounder RAS. This system produces 1270L/day of enriched effluent, with nutrient and suspended solids concentrations 20–100× that of ambient levels. This effluent was introduced with seawater to an upweller system stocked with bivalves at two densities for 4–6 weeks. Oysters (*Crassostrea virginica*, average shell height = 63.38 ± 0.86) and clams (*Mercenaria mercenaria*, average shell height = 16.65 ± 0.48) were used in separate experiments. Effluent nutrient composition (total nitrogen, total phosphorus, and total suspended solids) was analyzed from samples (collected twice weekly) taken upstream and downstream of each upweller. Bivalve growth was quantified by measurement of shell height at the start and end of each trial. Analysis of preliminary data suggests that both oysters and clams exhibited growth over the course of the experiments. Water samples are currently being processed to determine the impact of bivalve activity on effluent nutrient composition.

STATUS AND TRENDS OF BLACK ABALONE (*HALIOTIS CRACHERODII*): A PRELIMINARY APPROACH TO MODELING POPULATION VIABILITY. Melissa Neuman¹, John Butler¹, Brian Tissot² and Daniel Goodman³. ¹National Marine Fisheries Service, ²Washington State University Vancouver, ³Montana State University.

Black abalone, *Haliotis cracherodii*, was added to the National Marine Fisheries Service (NMFS) species of concern list in 1999 because of documented large declines, known threats and uncertainty regarding the future course of those threats. Although efforts have been made to protect surviving populations in California, USA through closure of the commercial fishery in 1993, the species continues to decline and a >90% reduction in abundance has been observed throughout >50% of the species range since the late 1980s. Heavy fishing pressure and disease have contributed to the observed decline. Expanding coastal development may increase human traffic in the intertidal and may intensify enforcement problems. Pollution, warming temperatures, and biological interactions with competitors/predators may also threaten remaining populations. NMFS must determine whether the rate and extent of black abalone population decline and the severity of risk are high enough to warrant a listing under the United States Endangered Species Act. In order to do this, a variety of tools are employed using the best available data to predict the probability distribution of long-term population trends. A population viability model is one tool that is being developed to assess species vulnerability through the analysis of the interplay of specific demographic parameters over a spatial array of habitat suitability and other possible forcing factors. Our scientific challenge is to identify important gaps in our understanding of this species' ecology that will allow us to deter-

mine what data needs to be collected for improving the estimates of the most influential parameters.

THE INFLUENCE OF EASTERN OYSTERS ON ECOLOGICAL PROCESSES IN CHESAPEAKE BAY: INSIGHTS FROM RECENT MODELING STUDIES. R. I. E. Newell, Horn Point Laboratory, University of Maryland.

Results from mathematical models will be reviewed to examine how changes in eastern oyster abundance may affect benthic-pelagic coupling in Chesapeake Bay. All models indicate that at current abundances of ~1 adult oyster m⁻² on historical oyster bottom, oysters exert negligible influence on water quality. At abundances of ~10 oysters m⁻², equivalent to the goal of the Chesapeake Bay Agreement of a 10-fold increase by 2010, models indicate that during warmer months oysters grazing on phytoplankton reduce turbidity to a level that significantly increases light availability for benthic plants. In cooler months, including during the spring phytoplankton bloom, oysters do not feed sufficiently actively to exert top-down grazer control. Biodeposition leads to appreciable removal of nitrogen through denitrification and burial. Resulting reduced phytoplankton biomass decreases microbial degradation of carbon beneath the pycnocline and increases oxygen concentration in bottom water. At ~100 oysters m⁻², which is the estimated pre-colonial density, models indicate that oysters can exert a profound influence on water quality. Even though such ecosystem services are extremely valuable, the challenge is how to restore oysters in the face of relentless harvest pressure, disease epizootics, and the siltation of the cultch essential for larval settlement. Closure of the public fishery and the development of oyster aquaculture would help increase oyster abundances. An absence of leadership is preventing these necessary changes from occurring; indeed, management decisions often exacerbate the problem, such as the recent opening of Maryland oyster bars to the once illegal practice of oyster dredging.

CHANGES IN SHELL STRENGTH OF *CRASSOSTREA VIRGINICA* AND *CRASSOSTREA ARIAKENSIS* IN RESPONSE TO CRAB PREDATORS FROM CHESAPEAKE BAY. Roger I. E. Newell, Victor S. Kennedy and Kristi S. Shaw, Horn Point Laboratory, UMCES.

If *C. ariakensis* were to be introduced to Chesapeake Bay it is unknown if its abundance would be controlled by the same predators that affect *C. virginica* populations. In replicated laboratory studies, we compared the relative susceptibility of juvenile diploids (shell height <25 mm) of both oyster species to five species of potential crab predators. We tested two species of mesohaline

mud crab, *Rhithropanopeus harrisi* [carapace width 6–16 mm] and *Eurypanopeus demissus* [6–18 mm]), two species of polyhaline mud crab *Panopeus herbstii* [9–29 mm] and *Dyspanopeus sayi* [8–20 mm], and the euryhaline blue crab, *Callinectes sapidus* [35–65 mm]. We found that all four species of mud crab and the blue crab significantly ($P < 0.05$) preferentially consumed *C. ariakensis* compared to *C. virginica*. We hypothesized that this differential predation may stem from differences in shell strength between the two species of oysters. Using an Instron load compression instrument we found that the strength of the upper valve of *C. ariakensis* was ~50% lower than for comparably sized *C. virginica*. Oysters of both species grown for 54 d in the presence of (but protected from) blue crabs exhibited different responses. *C. ariakensis* grew denser shells (total weight/shell area) that approximately doubled their compression strength compared to same species control oysters. The shell strength of *C. virginica* also approximately doubled, but these stronger shells had a significantly lower density than their controls. We conclude that both species of oysters respond morphologically to the presence of predators, although the response differs markedly between species.

DEVELOPMENT OF LANDSCAPE MODELS FOR PROTECTION AND RESTORATION OF FRESHWATER MUSSELS IN LARGE RIVERS. Teresa J. Newton¹, Michelle R. Bartsch¹, Jennie S. Sauer¹, Jeff J. Steuer¹ and Steve J. Zigler². ¹USGS, Upper Midwest Environmental Sciences Center, 2630 Fanta Reed Road, La Crosse, WI 54603, ²USGS, WI District Office, 8505 Research Way, Madison, WI 53562.

We assessed whether the spatial distribution of mussels could be predicted from physical, hydraulic, and biologic variables in a large floodplain river. Analyses of data from mussel beds at small (0.4 km) and moderate (6 km) spatial scales indicated that computed hydraulic variables (e.g., shear stress, Froude number) were more predictive than simple, measured variables (e.g., depth, velocity, substrate particle size). Similarly, classification tree models of mussel presence-absence in a 38-km reach of the river, which had a prediction success of ~75%, were largely driven by shear stress and substrate stability, but interactions with simple physical variables (e.g., slope) were also important. Moreover, discharge-specific models suggested that episodic events such as droughts and floods were more important in structuring mussel distributions than conditions during average flows. Because mussel species differ in shell features that may influence displacement during high discharge events, we evaluated if sculptured, thick-shelled species occupied areas with higher hydraulic stresses, compared to non-sculptured, thin-shelled species. Classification tree models predicted the presence of all mussels, regardless of shell morphology, in areas with low to moderate hydraulic stresses under low and high flow conditions. Overall, our studies suggest that mussels are

influenced by a complex interaction of biotic and abiotic factors acting at various spatial scales, but that certain hydraulic variables can improve our ability to predict their spatial distribution in large rivers.

UNIONID FEEDING STRATEGIES. S. J. Nichols, U. S. Geological Survey, 1451 Green Rd., Ann Arbor, MI, 48105.

The continued decline of many unionid communities throughout North America has been attributed to many factors ranging from pollution to exotic species. However, one main factor, food supplies, is rarely discussed. This raises a question: are populations declining in some locations because critical food supplies are no longer present? A review of the current research on unionid feeding highlights our limited knowledge about dietary requirements. Feeding studies on wild populations have been limited because of the difficulties in separating assimilation from ingestion in filter-feeding organisms. Recent technological advances such as stable isotopes and C^{14} enrichment have provided some information on food selectivity and have shown that unionids feed on a wide range of items including algae, dissolved organic molecules and bacteria. But these studies have not detected any food resource partitioning between sympatric genera or species. All species, regardless of shell length, type of gill cirri, siphon structure, or physical location in the substrate, appear to feed on particles <29 microns and can obtain food from either planktonic or benthic sources. However, such apparent omnivory does not translate into easily-maintained adults under captive conditions. Without access to natural food supplies, adult unionids rarely thrive. Dietary supplements such as used for marine bivalves do not support adult survival, though larvae can be reared using marine algae. Apparent omnivory is obviously misleading regarding actual dietary needs. In-depth surveys of potential food resources in waters with healthy unionid populations are critically needed to understand the relationship between food resources, unionid feeding strategies, and long-term survival.

PHYSIOLOGICAL BASES OF GENETICALLY DETERMINED VARIATION IN GROWTH OF BIVALVE LARVAE (*CRASSOSTREA GIGAS*). Douglas A. Pace¹, Adam G. Marsh², Patrick Leong³, Allison Green³, Dennis Hedgecock³ and Donal T. Manahan³. ¹AHF-210, Department of Biological Science, University of Southern California, Los Angeles, CA. 90089, ²University of Delaware, ³University of Southern California.

Variation in growth rates has been well documented in larval stages of bivalve molluscs. The endogenous processes that might contribute to individual-based variations in growth rates are not well understood. In this study, we used inbred lines of the Pacific

oyster, *Crassostrea gigas*, in a series of factorial crosses to produce families of larvae with different growth rates that were genetically set, even under identical environmental conditions of food and temperature. Growth rates of these larval families varied over a 5-fold range, from 3.4 to 17.6 $\mu\text{m day}^{-1}$. A suite of integrated measurements were applied to study growth variation in larvae, including: size, biochemical compositions, rates of acquisition of both dissolved and particulate nutrients, absorption efficiencies, metabolic rates, and enzyme activities. Fast-growing larvae had similar size-specific metabolic rates and capacities to slow-growing larvae, but the fast-growing larvae had significantly higher size-specific feeding rates. Also evident was the complex regulation of enzymatic activities responsible for ion transport (a metabolically expensive process in animals). Our results show that while feeding rates were important in explaining a portion of the growth differences, the regulation and internal allocation of metabolic energy played a large role in genetically-set growth rate variation. The larvae studied here clearly exhibited the phenomenon of hybrid vigor ("heterosis"). Our results will be discussed in the context of understanding the physiological bases of growth heterosis.

INVASION OF *CRASSOSTREA GIGAS* IN MARINE RESERVES: LOCAL REPRODUCTION OR DISPERSAL FROM ELSEWHERE? Dianna K. Padilla¹ and Terrie Klinger². ¹Stony Brook University, ²University of Washington.

The Pacific oyster, *Crassostrea gigas*, has been an important aquaculture species in the Pacific Northwest for >75 years. Because this species requires waters 19–20 °C for spawning, it has been considered a safe introduction, without the possibility of escape due to local reproduction limits. However, *C. gigas* has been invading rocky shores in the San Juan Archipelago, Washington for almost a decade, and is more abundant within than outside marine reserves. This recent invasion could be due to: 1) changes in temperature such that spawning can be induced, 2) thermal loading during low tide (mid-day) that allows oysters to spawn even though the water is cold, 3) evolution for spawning at lower temperatures, or 4) spawning or larval release elsewhere and dispersal into marine reserves and adjacent shores. We tested among these hypotheses by monitoring local temperatures and experiments to determine if oysters collected from the field will spawn when held at ambient water temperatures or at ambient water temperatures when exposed to a tidal cycle. We also tested whether larvae produced by local *C. gigas* were capable of development in the cold waters typical of the San Juans. These oysters do not appear able to spawn at temperatures <17–18 °C, and larval development even at 15 °C is slowed >3 times from development at 20 °C. Even in quiet bays, temperatures are not warm enough to

induce spawning. These data suggest that larval production elsewhere must be responsible for this invasion.

EVALUATION OF THE ANTIMALARIAL DRUG QUININE AS A POTENTIAL CHEMOTHERAPEUTIC AGENT FOR THE EASTERN OYSTER PARASITE, *P. MARINUS*. Christina Panko, Aswani Volety, Vincent Encomio and Jose Barreto. Florida Gulf Coast University, 10501 FGCU Blvd South, Ft. Myers, FL 33965.

Currently no anti-protozoal drug therapy exists in aquaculture to effectively treat or prevent *Perkinsus marinus* infections of the eastern oyster. Development of a chemotherapeutant specific for treating oysters infected with *P. marinus* or preventing disease may be an additional measure to avert physiological strain on aquaculture brood stock before spawning. Given the taxonomic proximity of *P. marinus* to Apicomplexans such as the malarial parasite, *Plasmodium* spp., the antimalarial drug Quinine was screened for drug sensitivity of cultured *P. marinus*. Following an acute challenge with varying concentrations of Quinine HCl, the viability of one strain of cultured meronts isolated from Laguna Madre, Texas oysters was determined using a dye reduction method. After a three hour exposure, the highest concentration tested, 50 $\mu\text{g/ml}$, had the most significant effect ($p = 0.000$) on parasite viability. Following assay optimization, six geographically distinct *P. marinus* isolates (ranging from Connecticut, New Jersey, Maryland, Virginia, Louisiana, and Texas) were exposed to 50 $\mu\text{g/ml}$ Quinine HCl to evaluate differences in susceptibility. The viability of all isolates significantly decreased after Quinine exposure. The Maryland and Virginia strains appeared to be more susceptible to treatment than the other isolates. Bearing in mind that hemocytes are integral component of the host innate immune system, the effect of Quinine on hemocyte viability was determined using a Neutral Red assay. The resulting information indicated the importance of examining the use of Quinine in mitigating *P. marinus* infections under *in vivo* conditions.

ESTABLISHING BASELINES FOR RECOVERY OF OYSTER (*CRASSOSTREA VIRGINICA*) POPULATIONS IN SOUTHEAST FLORIDA. Melanie L. Parker and William S. Arnold. Fish & Wildlife Research Institute, 100 Eighth Ave. SE, St. Petersburg, FL 33701.

Oysters occur in nearly all estuarine and nearshore waters along the Florida coast. Many of these waters have experienced altered patterns of water delivery and quality as a result of water management practices related to the St. John's River and Kissimmee River basins, Lake Okeechobee and the Everglades. Alterations in

freshwater flow have reduced or eliminated many oyster reefs and impacted both the timing and extent of oyster reproduction. The Comprehensive Everglades Restoration Program (CERP) is being implemented as a means of reinitiating natural freshwater flow to coastal waters in south Florida. Because of its wide distribution and essential habitat value, the eastern oyster is included in this program as a target species for monitoring and restoration. Changes in oyster distribution and abundance, reproductive development, disease incidence, and juvenile recruitment and growth are being monitored at several sites along the southeast coast of Florida including the St. Lucie estuary, Loxahatchee River, Lake Worth Lagoon and Biscayne Bay. Oyster populations in Tampa Bay, Mosquito Lagoon and Sebastian River are also being monitored as a background for comparison because these are outlier populations not affected by CERP water management practices. In January 2005, study sites were established within each estuary and monthly sampling of recruitment, reproductive development and disease incidence was initiated. Adult surveys were also conducted at each study site to determine oyster distribution and abundance. Preliminary results indicate that the pattern of degradation of oyster populations among estuaries is rather chaotic while the pattern within an estuary is more predictable.

IMPACTS OF THE TOXIC DINOFLAGELLATE *ALEXANDRIUM MONILATUM* ON THREE ECOLOGICALLY IMPORTANT SHELLFISH SPECIES. Susan E. Pate¹, JoAnn M. Burkholder¹ and Sandra E. Shumway². ¹North Carolina State University, ²University of Connecticut, Groton, CT.

Little is known regarding interactions between shellfish and *Alexandrium monilatum*, a toxigenic dinoflagellate species that forms blooms mostly in the Gulf of Mexico. Toxic *A. monilatum* has been linked to fish and invertebrate kills, and produces endotoxins with hemolytic and neurotoxic properties. We experimentally assessed responses of three ecologically important shellfish species to *A. monilatum* (toxic strain AMO3, NOAA National Ocean Service, Charleston, SC). In the first set of experiments, grazing studies were conducted with adult and juvenile eastern oysters (*Crassostrea virginica*), northern quahogs (*Mercenaria mercenaria*), and green mussels (*Perna viridis*), which inhabit areas where *A. monilatum* blooms occur. Clearance rates of each shellfish species were depressed when exposed to toxic *A. monilatum* (bloom density of ~550 cells/mL) alone or with nontoxic Instant Algae® *Pavlova*, in comparison to clearance rates of control animals that were fed a nontoxic dinoflagellate of similar size, *Alexandrium tamarense* (nontoxic clone CCMP115) and benign cryptophyte algae. Exposure to *A. monilatum* also significantly decreased shellfish valve gape. In the second set of experiments, bioassays were conducted to test survival of larval shellfish (*M. mercenaria*, *C. virginica*) exposed to *A. monilatum* as whole, unconstrained cells, cells held in dialysis tubing, or sonicated cells. Sonicated *A. monilatum* caused a significant decrease in larval

survival, in comparison to survival of the control larvae that were tested with nontoxic *A. tamarense*. Overall, these data indicate that *A. monilatum* blooms can adversely affect shellfish survival by reducing clearance rate and valve gape, affecting food intake, and inducing larval mortality.

OBSERVATIONS ON THE REPRODUCTIVE BIOLOGY OF THE HAIRY CRAB *HAPALOGASTER MERTENSII*, ON KODIAK ISLAND, ALASKA. Susan A. Payne, Jan A. Haaga and Bradley Stevens. AFSC NOAA Fisheries, Kodiak Fisheries Research Center, 301 Research Ct., Kodiak, AK 99615.

The reproductive biology of female *Hapalogaster mertensii*, an intertidal lithodid crab, from Kodiak Island, Alaska was observed in both the laboratory and field from 2000–2004. Larval release, in 2001, 2003, and 2004, occurred from February–June in the laboratory, and was not significantly different between years. Hatch duration in the individual crabs varied significantly between years and pairwise comparisons showed the following significant differences between years: 2001 (32.38 ± 3.37 days) > 2003 (22.62 ± 2.08 days) > 2004 (6.50 ± 3.37 days). The average number of larvae released was 214.75 ± 37.66 in 2001 and 157.38 ± 23.24 in 2003, and was not significantly different. Molting, mating, and the extrusion of a new clutch of eggs are not contiguous as in other lithodid crabs, but occur over a period of two to five months. Laboratory observations show that molting occurs twice in some females between hatching and extrusion. Possible mating behavior was observed twice, and occurred after the first molt, but was not associated with the molt or extrusion of new eggs. Egg extrusion in the lab was only observed in 2003 and occurred between 10 August and 10 November, and in the field in 2002 as early as July. Ovary incubation between the crabs was significantly different ranging from 187 to 244 days (224.67 ± 8.4288 , $P = 0.00$). Lab conditions appeared to mimic field observations for the timing of larval release and egg extrusion despite prolonged captivity of lab animals.

TRIPLOID *CRASSOSTREA ARIAKENSIS* AND *CRASSOSTREA VIRGINICA* GROWN AT FOUR SITES IN CHESAPEAKE BAY. Kennedy Paynter¹, Donald Meritt², Stan Allen³, Jake Goodwin¹ and Marey Chen¹. ¹University of Maryland, ²University of Maryland Center for Environmental Science, ³Virginia Institute of Marine Science.

Triploid suminoe oysters, *Crassostrea ariakensis*, and triploid eastern oysters, *Crassostrea virginica*, were produced nearly simultaneously in the hatchery and deployed in cages at four sites in Chesapeake Bay in April 2004. The four sites represented the broad range of salinities present in the Bay. The 'high' salinity site was in the York River near the Virginia Institute of Marine Science (VIMS; mean salinity 19 psu). The Patuxent River site had a mean salinity of 11 psu and the Choptank River site of 9 psu. The 'low' salinity site in the Severn River had a mean salinity of 6 psu.

Growth of both species was positively correlated with salinity. As of September 2004, no significant differences in size or disease prevalence existed between species at any site. Dermo, the disease caused by *Perkinsus marinus*, was detected in both species in July but only at the York River site. However, *C. ariakensis* grew more later in the year than did *C. virginica* and appeared to begin growing earlier in the following spring. Thus, *C. ariakensis* became significantly larger by June 2005. During the summer of 2005, *C. virginica* at the Choptank and York River sites grew more slowly than *C. ariakensis*, presumably due to *P. marinus* infections. Mean shell height of *C. ariakensis* at the York River site in October 2005 (deployed 19 months) was 140 mm compared to 105 mm in *C. virginica*. Physiological differences between the species apparently allow *C. ariakensis* to grow more actively at lower temperatures.

USING PCR TO DETERMINE THE ACCURACY OF MORPHOLOGICAL IDENTIFICATION OF *MERCENARIA MERCENARIA* LARVAE. Laurie Perino, Dianna Padilla and Michael Doall. Stony Brook University, Stony Brook, NY.

Identification of bivalve larvae in the field is an important aspect of fisheries management, restoration efforts and early warnings of invasive species. Traditional methods of identifying bivalve larvae are based on morphological characteristics of the larval shell. Problems occur when using this method because the larvae of many different species are very similar in shape and size, especially during the smaller D-stage. Newer molecular methods, including multiplex PCR, have been developed to aid in larval identification. The study presented here discusses the accuracy of morphological identification and provides error rates for misidentified larvae by using PCR to identify individual field collected larvae to species. For larvae suspected to be *Mercenaria mercenaria*, the rate of obtaining a false negative (identifying a larva as another species when it is actually *M. mercenaria*) was very low; however the rate of obtaining a false positive (identifying a larva as *M. mercenaria* when it is actually another species) was quite high. These error rates suggest that morphological characteristics are helpful in determining those larvae that are not the target species, but may lead to overestimations of densities of the target species due to overlaps in size and shape of different species.

ENRICHED ARTEMIA NAUPLII AS DIET FOR RED (*PARALITHODES CAMTSCHATICUS*) AND BLUE (*P. PLATYPUS*) KING CRAB LARVAE IN THE LABORATORY. Sara Persselin, NOAA Fisheries, Kodiak Fisheries Research Center, 301 Research Ct., Kodiak, AK 99615.

Newly-hatched unenriched *Artemia* nauplii are often the primary diet in culturing red (*Paralithodes camtschaticus*) and blue (*P. platypus*) king crab larvae in the laboratory. Although this diet allows survival to the first juvenile crab stage (C1), rates are sub-optimal. This work reports on studies over the last two years

investigating whether diets of enriched *Artemia* nauplii improve survival of red (RKC) and blue (BKC) king crab larvae. In 2003, RKC larvae were fed one of seven diets: (1) newly-hatched unenriched *Artemia*, (2–5) *Artemia* nauplii enriched with the microalga *Rhodomonas salina*, *Isochrysis* sp., *Thalassiosira nordenskiöldii*, or *T. aestivalis*, or (6–7) *Artemia* nauplii enriched with a commercial enrichment product, *Isochrysis* paste or Algamac 3050. The treatment that resulted in the highest survival to the non-feeding glaucothoe stage was *T. nordenskiöldii* (73%) and the treatment that resulted in the highest survival to C1 was *Isochrysis* paste (63%). Lowest survival to both stages occurred in the newly-hatched nauplii treatments (42% and 30%). Based on these results, BKC larvae were fed one of four diets in 2004: 1) *Artemia* nauplii enriched with the diatom *T. nordenskiöldii*, 2) *Artemia* nauplii enriched with frozen *Isochrysis* paste, 3) newly-hatched unenriched *Artemia* with *T. nordenskiöldii* added to the culture water and 4) no food. The treatment that resulted in the highest survival through C1 was newly-hatched *Artemia* with *T. nordenskiöldii* added to the culture water (91.7%). This diet is superior to either enriched *Artemia* nauplii or unenriched newly-hatched *Artemia* for king crab larvae cultured in the laboratory.

SITE-SPECIFIC GROWTH RATES OF ATLANTIC SURF CLAMS, *SPISULA SOLIDISSIMA*, FROM THE MIDDLE ATLANTIC BIGHT. Adriana Picariello, Roger Mann and Juliana M. Harding. The Virginia Institute of Marine Science, P.O. Box 1346, Gloucester Point, VA 23062.

In recent years, the general distribution of the Atlantic Surf clam, *Spisula solidissima*, along the east coast of the USA has undergone a dramatic shift both northward and into deeper water. This observation is based on 20 years of NOAA/NMFS/NEFSC stock assessments, with sampling from 1999 to the present indicating that this distribution shift has occurred. We examined surf clam growth from different locations along the current distribution. These locations included animals from both the southern and northern areas within the distribution as well as both inshore and offshore locations within these areas. Samples included a size range of animals 32 mm to 180 mm in shell length. Surf clam ages were determined by counting growth bands in the chondrophore. We present and compare estimates of age structure and growth from surf clam populations along a latitudinal and bathymetric gradient. Fitted growth curves were compared across and within sites.

TEMPORAL EXPRESSION OF GENETIC LOAD IN TWO FAMILIES OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS*. Louis Plough, University of Southern California.

Discovery of a large number of deleterious recessive mutations (genetic load) in the Pacific oyster (Launey & Hedgecock 2001, Genetics 159:255) explains distorted segregation ratios, seen widely in bivalves, and supports the dominance theory of heterosis

and inbreeding depression, for which there is substantial evidence. However, the fine scale mapping location and temporal expression of these deleterious alleles has not been well characterized. Previous experiments to map genetic load in the Pacific oyster had relatively poor genomic coverage and analyzed only two time points. We are attempting more complete genome coverage, based on a consensus microsatellite linkage map, evaluating over 90 markers and sampling larvae every day for thirty days post fertilization. Using inbred lines from wild populations and classical crossbreeding experiments, we are analyzing segregation ratios for 50 informative microsatellite DNA markers in larvae at 30 days post fertilization from an F_2 and F_3 hybrid family. We look for deviations from expected Mendelian inheritance ratios, owing presumably to selection against identical-by-descent homozygotes linked to nearby markers, and apply a linked selection model to estimate the number of lethal genes in the wild founders. We see, for example, one distortion on linkage group 9, where microsatellite *ucdCgi189* has only three homozygous genotypes of an expected 18 ($N = 66$). We are then following the distorted markers back in time to determine when the deleterious alleles to which they are linked were first expressed in development.

MEASURING SUCCESS IN OYSTER REEF RESTORATION: APPLICATION OF STANDARDIZED MEASURES AND TESTS OF APPROACHES. Martin H. Posey¹, Troy D. Alphin², Loren Coen³, Keith Walters⁴ and Dara Wilber⁵. ¹Department of Biology and Marine Biology, UNC-Wilmington, ²Center for Marine Science, UNC-Wilmington, ³Marine Resources Research Institute, SCDNR, ⁴Department of Marine Science, Coastal Carolina University, ⁵Grice Marine Program, College of Charleston.

Oysters along the Atlantic and Gulf coasts of North America have supported a historically important commercially fishery. Oysters are also increasingly recognized as key components of coastal ecosystems, providing habitat for transient and resident fauna, affecting particulate concentrations in overlying waters, reducing wave energy along sensitive shorelines and influencing local biogeochemical cycling. With a decline in oysters along much of the Atlantic coast, there is increased attention to restoring reefs through shell planting efforts. However, the lack of long-term monitoring using standardized methodologies that target both population and ecosystem functions has been an impediment to assessing the success of many restoration projects. In 2004, researchers at a SeaGrant-sponsored workshop proposed a set of sampling criteria and methodologies to provide standardized population and ecosystem measures for assessing the success of oyster restoration projects. We are applying these standardized measures to a series of restored reefs of varying ages along the central and southeast North Carolina coast. This includes comparison of selected habitat and population functions to reference reefs as well as examining the influence of seeding (placing hatchery oysters on

the reef at the time of creation), varying tidal position (intertidal to shallow subtidal), and landscape attributes, such as shell depth and proximity of adjacent habitat types, in reef establishment. This project will provide a comparison among different restoration designs as well as providing information on habitat function in a standardized form that can be compared among studies.

UNDERSTANDING *CRASSOSTREA GIGAS* POPULATION VARIABILITY USING A GENETICS-BASED MODEL. Eric N. Powell¹, John M. Klinck², Dennis Hedgecock³ and Eileen E. Hofmann². ¹Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Ave., Port Norris, NJ 08349, ²Old Dominion University, ³University of Southern California.

Survival and recruitment of marine bivalve larvae represent the interplay of environmental, biological, and physiological processes. However, the genetic characteristics of individual members of a population provide an overlay that determines the overall population response to exogenous and endogenous forces. This study describes the first genetically-based model developed for a marine bivalve species, *Crassostrea gigas*, that can be coupled to more traditional models describing animal growth and development. Explicit inclusion of genetic structure allows a mechanistic understanding of variability in growth, survival, and recruitment. The individual-based genetics model simulates generational changes in population genotype as a function of the number of parents and their genotypes. Each individual has 10 pairs of chromosomes, with multiple genes per chromosome and up to four alleles per gene. Some genes affect fitness by varying the chance of mortality; among these are homozygous recessives that are always lethal. The model structure allows genetic mutation and recombination, tracks male and female individuals by means of a sex gene, and permits the effective number of broodstock to be a small percentage of the total adult population. Multi-generational simulations show the disappearance of alleles, a decrease in heterozygosity, and a low effective population number, when only a few parents produce successful progeny and maintain the population yearly. Predicted sex ratios match observations, including the shift from male to female dominance with increasing size. Homozygous recessive genes develop in the population through mutation and slowly accumulate until common enough to affect population dynamics, which then restrains further increases.

COPPER IS AN ESSENTIAL NUTRIENT AND POTENTIAL TOXICANT IN THE DIET OF THE SEA URCHIN (*LYTECHINUS VARIEGATUS*). Mickie L. Powell¹, W. T. Jones¹, V. K. Gibbs¹, H. S. Hammer¹, J. M. Lawrence² and A. L. Lawrence³. ¹University of Alabama at Birmingham, Birmingham, AL, ²University of South Florida, ³Texas A&M University System.

Due to worldwide overfishing, scientists are currently developing stock enhancement and aquaculture techniques for sea urchins. Successful culture of sea urchins requires a formulated feed

that fulfills all nutritional requirements. Copper is an essential micronutrient in the diets of most animals. It is a component of many enzymes involved in energy production and in the protection of cells from free radicals. Excessive levels in the diet can be toxic. Small (ca. 13 g wet weight) *L. variegatus* were fed formulated feeds with low, medium, or high levels of copper for 12 weeks (calculated at 6, 47 and 160 ppm; levels based on established dietary levels for other marine invertebrates, supplemented as CuSO_4). Under these experimental conditions, wet weights of individuals fed a medium level of copper were slightly higher (43.2 ± 1.2 ; $P = 0.069$) than those fed low and high levels (39.9 ± 1.2 , and 40.3 ± 1.7 g wet weight, respectively). Gonad and gut wet weights were significantly lower ($P < 0.003$) in the high copper diet (6.9 ± 2.5 , 7.0 ± 3.6 and 5.0 ± 1.6 g gonad wet weight and 0.97 ± 0.04 , 1.1 ± 0.06 and 0.83 ± 0.04 g gut wet weight for low, medium and high levels, respectively). However, in the absence of copper supplementation survivorship decreased to 87.5% on the low copper feed. These data suggest that dietary copper is essential for normal physiological function, but can be toxic at high levels.

VIBRIO PARAHAEMOLYTICUS IN ALASKA: AN AGGRESSIVE RESPONSE TO A POTENTIAL CRISIS. Raymond RaLonde, Alaska Sea Grant Program, University of Alaska, Anchorage, AK 99501.

Oyster farmers in Prince William Sound, during the summer of 2004, were devastated by an outbreak of human illness caused *Vibrio parahaemolyticus* (Vp). With 63 confirmed cases, the outbreak was the second largest recorded in the United States history.

The United States Food and Drug Administration (FDA) is concerned about the Prince William Sound outbreak. The first serious problem is that the O6:K18 serotype, while similar to an isolate from the state of Washington, is extremely virulent, causing illness in concentrations as low as 3.5 bacteria per gram. In addition, over 76% of the environmental samples, tested positive for pathogenic Vp, while the worldwide historical averages less than 1%. Both of these factors indicate an unprecedented event that may have nationwide implications in further development of seafood safety standards.

As a follow-up to the 2004 outbreak, a statewide investigation involving the industry, Alaska Department of Environmental Conservation, FDA Gulf Coast Shellfish Laboratory, and the University of Alaska Sea Grant Program was implemented during the summer of 2005. The objectives of the study were to determine the extent of Vp in environmental samples in Prince William Sound, determine if Vp was present at oyster farms outside of Prince William Sound, and to test changes in aquaculture practices as preventative measures against Vp accumulation. Preliminary results indicate that Vp is broadly distributed in environmental

samples in Prince William Sound, and prompt intervention and temperature control was effective in preventing Vp illness from culture Pacific oysters.

MICROSATELLITE ASSESSMENT OF GENE FLOW IN AMBLEMA PLICATA IN THE OUACHITA HIGHLANDS OF SOUTHEASTERN OKLAHOMA. Kathleen Reagan¹ and Caryn Vaughn². ¹University of Oklahoma, Oklahoma Biological Survey, ²University of Oklahoma, Director-Oklahoma Biological Survey.

Appreciation of genetic diversity in unionids is essential to their preservation. Understanding how habitat perturbations, particularly those that fragment populations, affect this genetic diversity will provide information for better management of their natural habitats. We are examining genetic diversity and relatedness within a common mussel species, *Ambelma plicata*, from three rivers in the Ouachita Highlands of southeastern Oklahoma that are fragmented to varying degrees, due to impoundments. We sampled *A. plicata* tissue from ten sites across the Little (N = 8), Glover (N = 1) and MT. Fork (N = 1) Rivers. At each of these sites, mussels were sampled from 15, randomly placed, 0.25 m² quadrats. Tissue samples consisting of 20–40 µg of mantle tissue were clipped from a minimum of 30 individuals per site. A subsample of mussel individuals was taken from each site for shell thin-sectioning to determine age. Microsatellite markers will be used to examine both genetic diversity and relatedness of *A. plicata* within and between sites. This will enable us to determine the impacts of impoundments on gene flow.

MOLECULAR MARKERS FOR POPULATION STUDIES, SELECTIVE BREEDING AND PARENTAGE ASSIGNMENTS IN THE HARD CLAM (MERCENARIA MERCENARIA). Kimberly S. Reece¹, Gail P. Scott¹, Ryan B. Carnegie¹, Lisa Ragone Calvo², Eugene M. Bureson¹ and Mark D. Camara³. ¹VIMS, The College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062, ²Haskin Shellfish Research Laboratory, Rutgers University, ³USDA, ARS, OSU, Hatfield Marine Science Center.

The hard clam (*Mercenaria mercenaria*) industry has been heavily impacted by Quahog Parasite Unknown (QPX), which had caused substantial mortality in cultured clams at some sites along the eastern seaboard of the USA. Selective breeding of clams for traits such as disease resistance, enhanced growth rate and low salinity tolerance might provide stocks that significantly improve harvest yields in particular regions. Stocks derived from geo-

graphically distinct wild broodstock demonstrate differential susceptibility to QPX, suggesting a genetic basis for disease resistance. Side-by-side field experiments have shown significantly higher QPX prevalence in stocks from Florida and South Carolina compared to that observed in northern stocks (VA, NJ, MA). Unfortunately, genetic improvement efforts in bivalves are hampered by difficulties inherent in maintaining individually reared families in order to address genetic questions, and in developing elite genetic stocks without severe inbreeding depression. Molecular genetic markers can be used to assign individuals to families following field grow-out challenges and to facilitate maintenance of genetic diversity in stocks. For disease selection challenges, families can be mixed in the field and multi-locus genotypes can be used to assign individual progeny to parents or to reconstruct sibling relationships retrospectively. Individuals used for subsequent generation spawns can be selected based on genetic profiles to maximize diversity and genetic profiles of populations and stocks allow examination of genetic differentiation. We have developed both microsatellite and single nucleotide polymorphism (SNP) markers for *M. mercenaria* and are testing them for the ability to do parentage assignments and stock differentiation.

GENETIC CONSIDERATIONS IN BROODSTOCK SELECTION FOR OYSTER REEF RESTORATION. Kimberly S. Reece¹, Jens Carlsson¹, Jan F. Cordes¹, Ryan B. Carnegie¹ and Mark D. Camara². ¹VIMS, The College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062, ²USDA, ARS, OSU, Hatfield Marine Science Center.

Diseases caused by the parasites, *Perkinsus marinus* and *Haplosporidium nelsoni*, contributed to decline of native *Crassostrea virginica* populations in the eastern USA, and slowed their recovery. Recently, oyster restoration strategies have focused on improving tolerance to these parasites by planting selectively bred strains in Chesapeake Bay. Enhanced parasite tolerance in domesticated stocks might translate to increased chances of survival and reproductive success relative to wild populations. In addition, disease resistance genes from selected strains might introgress into wild populations through interbreeding. Genetic variation, however, is typically greatly reduced in hatchery lines compared to natural populations and depending on genotypic profiles, as well as relative census and effective population sizes, interbreeding with planted hatchery strains could reduce diversity in wild populations. Oyster populations in the Bay might become genetically less resilient in the face of future disease or environmental challenges. Understanding the genetic mechanisms of disease resistance and interactions between deployed hatchery stocks and wild populations is key to assessing the impact, positive or negative, of such oyster restoration strategies. Many hatchery stocks being used for restoration in Chesapeake Bay have unique genetic profiles dis-

tinguishing them from local wild populations. We are using molecular markers to evaluate the breeding success of deployed oysters and conducting surveys to examine the impact of disease on various populations and selected stocks. Genotypic data enables us to assign individuals to either local native populations, deployed oyster strains or putative hybrid groups, and disease data provides information on relative disease tolerances of the different groups.

REPRODUCTIVE CYCLE OF THE RAZOR CLAM *SOLEN MARGINATUS* (PULTENEY 1799) IN SPAIN. A COMPARATIVE STUDY IN THREE DIFFERENT PLACES. A. Remacha-Triviño, University of Rhode Island, Department of Fisheries, Animal and Veterinary Sciences, 20A Woodward Hall, RI 02881.

The reproductive cycle of the razor clam, *Solen marginatus*, (Pulteney 1799) is studied in three different places of Spain through time. Sampling was performed in the natural beds of: Eo Estuary (NW Spain) in 1994–95, Santander Bay (N Spain) in 1998–99 and Terrón Estuary (SW Spain) in 1999. In Eo, Santander and Terrón, respectively; phase 0 (resting stage) occurred in July–August, September–October and August–September, phase I (early gametogenesis) happened in: August–October, October–December and September–November, phase II (late gametogenesis) was developed in November–April, January–May and December–April and phase III (reproduction) took place in: May–June, June–August and May–July. Two new approaches oriented to the fast monitoring of the gametogenic cycle of the species based on sequential mean drained soft parts weights obtained by simulation and on the macroscopic observation of the gonad are presented.

QUANTIFICATION OF *PERKINSUS MARINUS* IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA* USING MODERN STEREOLOGICAL TECHNIQUES. Antonio Remacha-Triviño¹, Dodi Borsay-Horowitz², Christopher Dungan³, Ximo Gual-Arnau⁴, Javier Gómez-León¹ and Marta Gómez-Chiarri¹. ¹University of Rhode Island, 20A Woodward Hall, Kingston, USA, ²US EPA, Atlantic Ecology Division, ³Maryland DNR, Cooperative Oxford Laboratory, ⁴Universitat Jaume I, Castelló, Spain.

Dermo disease, caused by the protozoan parasites *Perkinsus* spp., is responsible for high mortalities of bivalve molluscs worldwide. In order to improve the knowledge of the pathogenesis of Dermo, accurate techniques to estimate the number of parasites in tissue sections are required. This study is aimed to quantify the number and tissue distribution of different stages of *P. marinus* in a natural population of *Crassostrea virginica* from Wickford

(Rhode Island, US) by the application of modern stereology and immunohistochemistry. Mean total number of trophozoites in eight oysters collected in July 2005, of mean shell length (mean \pm SD) of 101.2 ± 5.2 mm, were (mean \pm SE) 11.80 ± 3.91 million and 11.55 ± 3.88 million for the optical disector and optical fractionator methods respectively. The mean empirical error between both stereological approaches was $3.8 \pm 1.0\%$. Trophozoites were detected intracellularly in the following tissues: intestine (30.1%), Leydig tissue (21.3%), hemocytes (14.9%), digestive gland (11.4%), gills (6.1%), connective tissues (except Leydig and mantle) (5.7%), gonads (4.1%), palps (2.2%), muscle (1.9%), mantle connective (0.8%), pericardium (0.7%), mantle epithelium (0.1%), and heart (0.1%). The remaining 0.6% of trophozoites were found extracellularly throughout different tissues. Percentages of trophozoite stages were (mean \pm SE): large, log-phase trophonts (*i. e.* signet-rings): $97.0 \pm 1.2\%$; meronts: $2.0 \pm 0.9\%$; clusters of small, log-phase trophonts (*i. e.* merozoites): $1.0 \pm 0.5\%$. These techniques could be useful to follow parasite distribution and progression in experimental infections, and further explore mechanisms of dermo pathogenesis.

HERPES VIRUSES INFECTING BIVALVES: A REVIEW.

T. Renault, IFREMER, La Tremblade, France.

Particles morphologically similar to herpes viruses were first detected in an invertebrate (the Eastern oyster, *Crassostrea virginica*) in 1972. Herpes-like viruses have since been identified in various marine bivalve species throughout the world, including the Pacific oyster, *Crassostrea gigas*, the European flat oyster, *Ostrea edulis*, the Antipodean flat oyster, *Ostrea angasi*, the Chilean oyster, *Tiostrea chilensis*, the carpet shell clam, *Ruditapes decussatus*, the Manila clam, *Ruditapes philippinarum* and the great scallop, *Pecten maximus*. Infections are often associated with sporadic episodes of high mortality among larvae and juveniles. PCR-based diagnostic methods have facilitated epidemiological investigations showing that healthy adult animals can harbour the viral genome. Transmission experiments have demonstrated the pathogenicity of the virus, and indicated that a single species is probably responsible for all the infections observed. The virus isolated from infected *C. gigas* larvae has been formally classified as a member of the *Herpesviridae* under the name ostreid herpesvirus 1 (OsHV-1). Characterization of the genome yielded an estimated size of 207 kbp. The capsid morphology and genome sequence of OsHV-1 have been studied in order to assess its phylogenetic status in relation to vertebrate herpes viruses. The conserved gene that comes closest to being herpes virus-specific encodes the putative ATPase subunit of the terminase, an enzyme complex involved in packaging viral DNA into preformed capsids. Moreover, similarities between the two groups in capsid structure and mechanisms of

capsid maturation tip the balance of evidence in favour of a common origin.

OYSTER HERPES VIRUS 1 (OSHV-1) INDUCED GENES IN THE PACIFIC OYSTER (*CRASSOSTREA GIGAS*). **T. Renault, N. Faury, V. Barbosa-Solomieu, K. Moreau, C. Brunetière, D. Saulnier and J.-F. Pepin**, IFREMER, La Tremblade, France.

Since 1972, several herpes-like virus infections have been reported among different bivalve species around the world. Viral detection was often associated with high mortality rates in spat and larvae of bivalves, including Pacific oyster (*Crassostrea gigas*). The genome characterization of the virus infecting *C. gigas* allowed it to be included in the *Herpesviridae* family as an unassigned member and named Oyster Herpes virus 1 (OsHV-1). The specific objective of the present study was to search for OsHV-1-induced genes expressed in adult *C. gigas* oysters. The suppression subtractive hybridisation (SSH) technique has been used. Oyster haemocytes in contact with infected and non-infected ground larvae were used to extract RNA. Briefly, cDNA was obtained from 1 μ g of each hemocyte RNA (control and after virus contact) using the SMART PCR cDNA Synthesis Kit (Clontech), which allowed the full-length amplification of cDNA from mRNA transcripts. A SSH assay was then performed using the PCR-Select cDNA Subtraction Kit (Clontech). The forward-subtracted sample (genes present or up-regulated in presence of the virus) was then used in PCR to amplify the differentially expressed sequences. Cloned PCR products were sequenced using a 3100 Avant Genetic analyser ABI prism (Applied Biosystem). BlastX analysis of the sequenced differentially regulated clones resulted in unique homologues being identified of which some have never been reported previously in any bivalve species. One of the promising candidates corresponds to a homolog with glypican 6 precursor genes. Glypican 6 is a cell surface proteoglycan bearing heparan sulfate. Heparan sulfate proteoglycans serve as cellular receptors for herpes viruses.

ECOLOGICAL SERVICES RENDERED BY CULTURED EASTERN OYSTERS. **Robert B. Rheault**, Moonstone Oysters, 1121 Mooresfield Rd., Wakefield RI 02879.

It has been shown that wild and cultured oysters provide many ecological services that benefit both the environment and wild oyster stocks. (Shumway et al. 2003, Newell 2004, 2002) The services rendered by commercial oyster aquaculture include: removal of nutrients (both by harvest and enhanced bacterial denitrification); improving water clarity and water quality by enhance-

ing sedimentation; adding larvae to the wild; sequestering tons of carbon and creating a structurally diverse habitat for other marine organisms.

When an oyster is harvested approximately 0.52 g N and 0.16 g P are physically and permanently removed from the marine environment. The combined harvest of approximately 700 million cultured Eastern Oysters removes 357 metric tons of nitrogen and 110 metric tons of phosphorus from the marine environment annually. Additional nitrogen is removed by denitrification associated with these farms. These oysters sequestered 51,559 metric tons of carbon in their shell and released an estimated 1.7×10^{15} larvae into the wild. Cultured oysters clear an estimated 94 million cu meters of water daily, while thousands of acres of oyster culture grounds provide a habitat for billions of diverse marine organisms.

These factors were considered in light of the recent effort to list the Eastern oyster as an endangered species. Unavoidable damage to the oyster culture industry would have severe negative impacts on wild populations and coastal water quality as well.

ASSESSMENT OF THREE STAINS INTERNALLY MARKING MOLLUSC SHELLS OF *CONCHOLEPAS CONCHOLEPAS* AND *MESODESMA DONACIUM*. José M. Riascos V.¹, Nury Guzmán², Jürgen Laudien³, Olaf Heilmayer³ and Marcelo Oliva¹. ¹Universidad de Antofagasta, Investigaciones Oceanológicas, ²Institut de Recherche pour le Développement, Bondy Cedex, FR, ³Alfred-Wegener Institute for Polar and Marine Research.

Different stains have been used to internally mark the calcified structures of mollusc shells and thereafter for the validation of growth estimates. As an interspecific variation in marking success is known, an assessment of suitability is necessary. The potential of Calcein, Alizarin red and Strontium-chloride-hexahydrate (SCH) was investigated for the gastropod, *Concholepas concholepas*, and the surfclam, *Mesodesma donacium*, two molluscs of commercial importance in Chile. Wild specimens collected off Antofagasta, Northern Chile, were marked using two concentrations of each stain and two immersion periods as well as a control. After immersion, animals were reared for 20 days to allow growth. Mortality, body condition and growth were measured to assess the effects of treatments. For the detection of the incorporated marks, individuals were culled and shell sections analyzed under a fluorescence microscope (Calcein, Alizarin) and a scanning electron microscope (SCH), respectively. The treatments did not show significant effects on mortality and body condition. However, the growth rate of *C. concholepas* was significantly different ($P < 0.05$) among stains (SCH < Alizarin < Calcein). Calcein markings were successful in all treatments (50 and 100 mg l⁻¹, 3 and 6 hrs.) whereas Alizarin only yielded comparable results with 100 mg l⁻¹ and 6 hrs. SCH just produced faint marks, even at high concentrations. Markings in *C. concholepas* were clearer compared to *M.*

donacium, which can be attributed to the gastropod's fast growth rate (0.43 $\mu\text{m d}^{-1}$). Calcein was assumed to be the best marker and did not considerably affect the viability of the species studied.

INTERACTIONS BETWEEN THE SURFCLAM (*MESODESMA DONACIUM*) AND THE COMMENSAL POLYCHAETA (*POLYDORA BIOCCIPITALIS*) IN NORTHERN CHILE. José M. Riascos V.¹, Olaf Heilmayer², Marcelo Oliva³ and Jürgen Laudien². ¹Universidad de Antofagasta, Investigaciones Oceanológicas, ²Alfred-Wegener Institute for Polar and Marine Research, ³Universidad de Antofagasta, Investigaciones Oceanológicas.

Although the surfclam, *Mesodesma donacium*, is one of the most important species for shellfisheries in Chile and the infestation by the symbiotic polychaete, *Polydora bioccipitalis*, reaches 31.4%, nothing is known about this species association. Monthly samples from Hornitos (Northern Chile) were collected to determine the shell length (anterior-posterior) when commensalism first occurs, and its effect on the body condition index (BCI = dry tissue mass/internal cavity volume $\times 100$). The temporal pattern of the symbiosis was studied by measuring the thickness of the blisters walls formed in the bivalve shell as an estimation of duration of the association. In addition, a laboratory experiment was performed to assess if the commensal relationship affects the growth rate of the host. Preliminary results indicate that the symbiosis can only be found in clams larger than 33.3 mm. As *M. donacium* undergoes a migration from the intertidal (juveniles) to the lower subtidal (post-juveniles and adults) during its life cycle, it appears that the symbiosis only occurs during a later ontogenetic stage when individuals inhabit the subtidal level. BCI was significantly different ($P < 0.05$) between hosting and non-hosting clams. Although the internal shell cavity was smaller in hosting clams, thus affecting considerably the BCI, the proportion of dry tissue mass was not significantly different. This suggests that *M. donacium* is well adapted to the commensal. Thickness of blister walls showed differences (t-test, $P < 0.05$) between months: thinner blister walls were found in May, June and July, suggesting a seasonal pattern of the commensalism.

GENETIC STRUCTURE OF OYSTER REEFS ALONG THE ALABAMA GULF COAST. Gillian Richard and Charles Brockhouse. University of South Alabama, 307 N. University Blvd., LSCB Rm 124, Mobile, AL 36688.

The oyster bed productivity in areas, such as Mobile Bay, has abruptly declined in recent years despite the absence of fishing pressures. These declines have negatively affected the commercial

and recreational fisheries in Alabama and may have also influenced the Bay's natural ecosystem in unknown ways. In an attempt to increase oyster stocks in Mobile Bay, a restoration program has been initiated. To effectively manage an oyster reef restoration project an understanding of the genetic structure of the oyster population(s) and hence, the extent of local larval transport and genetic exchange among the oyster reefs in the natural environment is of considerable practical importance. This study has established a genetic map of the region by investigating the genetic variation and differentiation among five oyster reefs spanning the Alabama gulf coast. The results indicated high levels of genetic diversity within sampled reefs and F_{ST} revealed little genetic differentiation among the samples. An estimator of gene flow indicated that the main commercial oyster reef, Cedar Point Reef, is the primary source of recruits for the area.

CFD ANALYSIS OF SHELLFISH AQUACULTURE GEAR USED IN INTER-TIDAL AND SUB-TIDAL LOCATIONS.

John Richardson¹, Carter Newell², Dror Angel³, Tessa Getchis⁴, Andy Suhrbier⁵, Jonathan Davis⁶ and Daniel Cheney⁷. ¹Blue Hill Hydraulics Incorporated, ²Great Eastern Mussel Farms, ³Massachusetts Institute of Technology, ⁴Connecticut Sea Grant Extension Program, ⁵Pacific Shellfish Institute, ⁶Taylor Resources Baywater, Inc., ⁷Pacific Shellfish Institute.

An environmental and technical assessment of alternative methods used to cultivate bivalve shellfish was completed as part of the National Marine Aquaculture Initiative (NMAI). Included in the list of study sites were locations in Washington State and Connecticut where aquaculture is being carried out in inter-tidal and sub-tidal waters using bag-on-bottom, bag-on-rack, net-protected or cage culture methods. To evaluate the effectiveness of these methods used for shellfish aquaculture and to better understand their effect on the local environment, experimental and numerical studies of culture unit hydrodynamics were completed. These studies involved the acquisition of near-field velocity measurements, dye studies, and construction of three-dimensional numerical models based on computational fluid dynamics (CFD) techniques. Of particular interest are the use of fractional volume techniques to model nets and bags, and the use of a kinetics algorithm to calculate phytoplankton consumption within the culture units. These techniques allow the practitioner to accurately simulate three-dimensional flows through the different types of culture units and to estimate food availability within the culture units. The results of the modeling were used to help provide explanation of the field data sets, to identify "holes" in the data sets, and to compare the performance of the different shellfish aquaculture practices. The methods developed for this study can also be used as an aid to evaluate siting concerns and to customize gear designed to work optimally at specific locations.

LINKAGES BETWEEN CELLULAR BIOMARKER RESPONSES AND REPRODUCTIVE SUCCESS. Amy H. Ringwood¹, Charles J. Keppler², Jennifer Hoguet³ and Michel Gielazyn⁴. ¹University of North Carolina, Charlotte, Department of Biology, 9201 University Blvd., Charlotte, NC 28223, ²Marine Resources Research Institute, SCDNR, SC, ³College of Charleston, ⁴University of South Carolina.

An important issue for cellular biomarker assessments is whether they are related to higher level responses (e.g. are there linkages between cellular and organismal responses that could translate into population level effects?). The purpose of these studies was to evaluate if there were relationships between lysosomal destabilization or glutathione concentrations and gamete viability of oysters, *Crassostrea virginica*. Oysters were collected from reference and polluted field sites during the peak spawning period (May-June). Hepatopancreas (e.g. digestive gland) tissues were dissected and a portion was used immediately for lysosomal destabilization assays (based on neutral red retention), and glutathione concentrations were also determined for both hepatopancreas and gonadal tissues. Eggs and sperm from the same adults were also used to conduct embryo development assays with reference seawater collected from a clean site, site water, and also a range of Cd concentrations (the Cd exposures were used to determine if there were differences in susceptibility to pollutants). Baseline embryo development success (e.g. percent normal development when the assays were conducted with reference seawater or site water) was related to lysosomal destabilization, but not glutathione status. However, the susceptibility of embryos to metal exposures was related to glutathione status, i.e. sensitivity to Cd exposures increased with decreasing glutathione levels. These studies support the hypotheses that there are linkages between these cellular biomarker responses and embryo development success and susceptibility to pollutant stress. These kinds of effects on reproductive success could lead to subtle but significant long-term effects on recruitment and viability of oyster populations.

OXYTETRACYCLINE TREATMENT OF WITHERING SYNDROME IN RED ABALONE (*HALIOTIS RUFESCENS*).

Thea T. Robbins¹, Eric Rosenblum², Ronald Tjeerdema², James D. Moore¹ and Carolyn S. Friedman³. ¹California Department of Fish and Game, ²Department of Environmental Toxicology, University of California, Davis, ³University of Washington.

Since the mid 1980's the disease withering syndrome (WS) has severely impacted wild and cultured California abalone (*Haliotis* spp.). The causative agent of WS "*Candidatus Xenohaliotis californiensis*" infects gastrointestinal epithelia. The broad-spectrum antibiotic oxytetracycline (OTC) has been shown to control infec-

tions in cultured and broodstock abalone as a therapeutic in medicated feed. We examined the efficacy and pharmacokinetics of OTC in infected red abalone, *Haliotis rufescens*, medicated with an artificial diet containing 1.85% active OTC at a rate of 103.4 mg/kg abalone for 10, 20 or 30 days at 13.4°C. The medication was 97% effective in clearing RLP infections in the 10 day treatment and 100% in the 20 and 30 day treatments. Significant differences were observed in prevalence ($p < 0.0001$) and intensity of infection in post-esophagus ($p < 0.0001$) and digestive gland ($p < 0.05$) of treated abalone compared to untreated abalone. Survival was not appreciably different among treatments due to a thermal refuge from disease expression at low temperature; however during a sequential study at an elevated temperature of 17.3°C, unmedicated abalone suffered higher losses and developed clinical WS at a higher rate than medicated animals. Depletion dynamics in abalone tissues showed animals medicated for 10 days accumulated significantly less OTC than those medicated for 20 or 30 days with significantly lower OTC levels present in foot muscle samples relative to digestive gland samples ($P < 0.001$). In contrast, at 17.3°C abalone only accumulated half as much OTC as those at 13.4°C suggesting that both temperature and duration of medication are important regulators of OTC pharmacokinetics in abalone.

OVERVIEW AND APPLICATION OF BAY SCALLOP GENOMIC RESOURCES. Steven Roberts, Marine Biological Laboratory, 7 MBL Street, Woods Hole, MA 02543.

The bay scallop (*Argopecten irradians*) is a commercially important bivalve mollusc that supports culturally significant recreational fisheries along the East Coast of the United States. The bay scallop is also an excellent scientific model to study visual signal transduction, early development, and muscle physiology. Furthermore, like other bivalves, scallops are essential components in maintaining sustainable marine environments. In order to provide basic molecular tools to study scallop biology several approaches have been taken including differential display, degenerative primer based RT-PCR and small-scale expressed sequence tag projects. Several gene products from these combined efforts have been further characterized using comparative analysis of gene expression, *in silico* procedures, and recombinant protein systems. Expressed sequence tag derived genetic markers have been developed and used to evaluate stock enhancement. An overview of the molecular techniques employed will be presented including suggestions on how to develop similar efforts. Experimental results will be presented on transcripts associated with scallop early development and growth. This research was supported by the United States Department of Agriculture (grant #2003-35206-12834) and the County of Barnstable Massachusetts.

CHARACTERIZATION OF DIFFERENTIALLY EXPRESSED GENES FROM QPX: INSIGHT INTO POSSIBLE VIRULENCE MECHANISMS. Steven Roberts, Roxanna Smolowitz and Christina Romano, Marine Biological Laboratory, 7 MBL Street, Woods Hole, MA 02543.

Quahog Parasite Unknown (QPX) is a protist, genetically identified as belonging to the family Thraustochytridae in the phylum Labyrinthulomycota (slime mold). It proliferates by endospore formation and has been identified as a significant cause of hard clam mortality in the Northeast United States. QPX causes significant disease and mortality in both cultured and wild clam populations in the region. In order to begin to understand what genes are present in the extracellular proteins of QPX mucus and are associated with QPX virulence; we have started to characterize genes that are expressed in QPX under different conditions. In one experiment focused on temperature influences on gene regulation, QPX cultures were grown at 10°C and 21°C for 10 days. Following incubations, total RNA was extracted from cultures and several differentially expressed genes were identified using a differential display polymerase chain reaction technique (GeneFishing DEG System—Seegene). To our knowledge, these are all novel gene homologs in QPX as only rDNA sequences have been previously characterized. One of the genes upregulated at 10°C is a potassium channel protein, based on DNA sequence homology. Similar proteins have been shown to be important for other pathogens as they can inhibit phagocytosis. Additional transcripts and comparative gene expression analysis in QPX strains under different environmental conditions will be presented. The long term goal of this research is to provide resource managers with basic information on QPX biology that could be used to facilitate hard clam aquaculture and protect wild populations.

IMPLICATIONS OF HIGH-RESOLUTION GEOPHYSICAL TECHNIQUES IN OYSTER HABITAT IDENTIFICATION: CAPE FEAR RIVER, NORTH CAROLINA. Kassy Rodriguez, Nancy Grindlay, Lewis Abrams, Troy Alphin and Steven Artabane, University of North Carolina Wilmington.

Eastern oysters (*Crassostrea virginica*) are filter feeding organisms that settle in dense aggregates and positively impact water quality by providing a series of ecosystem functions, which include habitat for other organisms, filtration, and habitat stability. The United States Army Corps of Engineers created dredge spoil islands throughout the lower 20 km of North Carolina's Cape Fear River as a result of channel dredging. These activities have altered water flow and increased siltation, reducing the amount of hard substrate available for oyster spat settlement and growth. Currently, small amounts of hard substrate remain in the lower river

and routinely experience high over-spill events, followed by high mortality from a combination of competition and high sedimentation. Sidescan sonar and sub-bottom profiling systems were used to map four areas within a 15 km long section of the lower Cape Fear River to locate living and buried oyster reefs. The southernmost area contains living oysters, while the northernmost areas are along dredge spoil islands and are devoid of living populations, despite the presence of Indian middens, which may suggest a localized historic occurrence of oysters and the potential for buried oyster reefs. Potential buried reef locations have been identified for ground-verification. Hypothesizing that oysters should be able to grow where they once thrived, these data will be used to guide placement of oyster cultch. If these sites prove suitable for new oyster cultivation, this geophysical technique has important implications for the success of future oyster restoration projects in southeastern North Carolina.

RECRUITMENT AND SUCCESSION VARIABILITY IN OYSTER FOULING COMMUNITIES IN BAHIA SAN QUINTIN, BAJA CALIFORNIA, MEXICO. Laura F. Rodriguez, University of California, Davis, Section of Evolution and Ecology, Davis, CA 95616.

Bahia San Quintin is a shallow bay on the Pacific coast of the Baja California peninsula, Mexico. Historically dominated by soft sediment systems, the bay currently supports a locally important oyster aquaculture industry. In this system, oysters (*Crassostrea gigas*) are cultivated on ropes and remain suspended in the water column for about one year, until they attain market size. These systems provide a significant amount of available substrate for the development of diverse fouling communities, which are dominated by ascidians, sponges, bryozoans, and hydrozoans. These fouling communities harbor non-indigenous species, one of which is the Australian ascidian, *Microcosmus squamiger*. This ascidian can attain pest-like densities, completely covering oyster ropes and likely limiting the amount of food and dissolved oxygen accessible to the oysters. Oyster farmers view fouling communities as a nuisance that both harm their oyster crop and increase their handling time in cleaning and packaging oysters. To investigate the impact of these fouling communities on the oyster crop I have been taking monthly recruitment and community succession samples at three sites within Bahia San Quintin for the past two years (2004–2005). I used oyster shells as substrate panels to look at the abundance and prevalence of fouling organisms after 1, 2, 3, 6, and 12 month soaking periods. Results from this study establish recruitment patterns and variability, and community development and succession trends following recruitment. These results, coupled with seasonal and water temperature information, will help develop management options to mitigate impacts of detrimental fouling species.

OCEAN TEMPERATURE, FOOD ABUNDANCE AND DISEASE: CONTRIBUTORS TO REPRODUCTIVE FAILURE IN RED ABALONE. Laura K. Rogers^{1,2}, Richard F. Dondanville³, L. Ignacio Vilchis⁴, Mia J. Tegner^{4,*}, Beverly Braid², James D. Moore^{1,2}, and Paul K. Dayton⁴. ¹California Department of Fish and Game, ²U.C. Bodega Marine Laboratory, 2099 Westside Rd., Bodega Bay, CA 94923, ³5342 Winding View Trail, Santa Rosa, CA 95404, ⁴Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA 92093, ^{*}Deceased.

Changes in ocean climate can have dramatic, non-linear impacts on the population dynamics of marine invertebrate populations. We investigated the impacts of water temperature and other factors on reproduction in red abalone (*Haliotis rufescens*) (1) from the wild, (2) from laboratory experiments varying water temperature and kelp rations, and (3) disease exposure. We examined body morphology, gonad and digestive gland indices, and histology sections of gonad tissue to determine fecundity. All wild abalone had mature gametes and females averaged more than 2 million mature eggs. Males had total reproductive failure, with no sperm in their testes, at temperatures of 16°C and warmer suggesting a fixed upper thermal limit. Females continued to produce mature eggs at warm temperatures, but were sensitive to reductions in food quantity. No gametes were found in diseased abalone of either sex once their foot muscle started to shrink from disease. Diseased abalone could be distinguished from starved abalone by their abnormal gonad structure. Starved abalone had normal gonad structure, with some gametes, but dramatically reduced gonad (25% of wild) and digestive gland (45% of wild) indices. The temperature-mediated effects on reproduction of individual red abalone described here, combined with temperature's known impacts on abalone growth, kelp abundance and expression of disease, clearly demonstrate temperature's population level consequences. We suggest that temperature be explicitly incorporated into red abalone recovery and management planning since water temperature plays a large role in male fecundity and since ocean temperatures are predicted to rise in the future.

OYSTER RESTORATION IN AN URBAN LANDSCAPE: CHARACTERIZATION OF A BASIN-WIDE OYSTER POPULATION IN THE LYNNHAVEN RIVER, VIRGINIA. P. G. Ross¹, M. W. Luckenbach¹, A. J. Birch¹ and L. D. Coen². ¹VA Institute of Marine Science, College of William & Mary P.O. Box 350, Wachapreague, VA 23480, ²Marine Resources Research Institute, South Carolina Department of Natural Resources.

Historically in the Chesapeake Bay, quantitative evaluations of oyster reef restoration have focused on subtidal reefs utilizing fisheries-based metrics (e.g. abundance of market-sized, ~76 mm, oysters). Monitoring is typically initiated after restoration activities have been implemented, with few instances of coordinated data collection before, during and after restoration activities. Beginning in 2006, a large-scale oyster restoration effort, including habitat

and brood stock enhancement, is planned for the Lynnhaven River Basin, a small and relatively closed tidal sub-tributary of the lower Chesapeake Bay. In contrast to most other restoration sites in this region, the Lynnhaven Basin is heavily urbanized with extensive portions of the shoreline covered with stabilization structures such as concrete, wood or metal bulkheads and granite or concrete rubble that can be considered “non-traditional” habitats, which support substantial oyster densities. This type of habitat poses significant challenges for determining initial oyster population size within the basin and basin-level effects of subsequent restoration efforts. We report on characterization of the basin-wide oyster population (overall abundance and size distribution) prior to the fore mentioned restoration activities, including data collection techniques (e.g. sub-meter accuracy surveying Global Positioning Systems [GPS], integrated with an ArcView-based Geographic Information System [GIS]), and challenges regarding extrapolating oyster data to such a large region. Additionally, we describe the extent and relative proportion of varied habitats in this system along with habitat-specific oyster population parameters.

ROTATIONAL AREA MANAGEMENT IN THE NORTH-WEST ATLANTIC SEA SCALLOP FISHERY: ARE CURRENT MANAGEMENT STRATEGIES FLEXIBLE ENOUGH? David B. Rudders, William D. DuPaul and Noëlle Yochum. Virginia Institute of Marine Science, Gloucester Point, VA 23062.

Limiting fishing activities in certain areas has gained support as a method to conserve and enhance marine resources. Amendment #10 to the Sea Scallop Fishery Management Plan formally established area rotation as a regulatory strategy to protect aggregations of pre-recruit scallops to optimize gains in yield-per-recruit. The criterion for establishing and re-opening rotational closed areas is dependent upon estimates of the year-over-year growth expressed as a percentage increase of scallop biomass. This strategy is advantageous when large recruitment events are episodic in nature, resulting in a predominant year class. It is also effective because, historically, sea scallop recruitment has been highly variable. Recently, regular recruitment has been observed in the mid-Atlantic region, including the Elephant Trunk Closed Area (ETCA), which was established in July 2004 to protect a large 2002 year class. To evaluate this trend, a fixed grid survey was conducted in October 2005 using both a commercial and a NMFS survey dredge. Results indicate that while the 2002 year class that prompted the closure is present, additional recruitment events have taken place. The addition of these recruits complicates the use of biomass thresholds as triggers for closing and opening rotational management areas. The ETCA is scheduled for a limited opening in 2007. Managers have expressed concern that yield-per-recruit objectives will not be met and there is potential for discard related fishing mortality. We examined the flexibility of the criterion for rotational area man-

agement and various spatial and temporal harvesting strategies to optimize fishery yields and minimize non-harvest mortality.

THE EFFECT OF CONDITIONING HATCHERY-REARED GREEN SEA URCHINS TO LOW SALINITY ON SURVIVAL AND GROWTH IN THE FIELD. Michael P. Russell, Villanova University, Villanova, PA 19085.

Harvest data show a precipitous decline in the green sea urchin fishery (*Strongylocentrotus droebachiensis*) in the Gulf of Maine. This situation has prompted studies aimed at enhancing standing stocks by seeding formerly productive fishing grounds with hatchery-reared juveniles. One complicating factor is that these environments are subject to fluctuating salinity. Echinoderms are osmoconformers and generally do not tolerate brackish water. However, green urchins are exceptional in their abilities to acclimate to periodic exposures to low salinity. We conducted a field study to assess the efficacy of conditioning hatchery-reared juveniles to hyposaline conditions prior to releasing them at sites where low-salinity conditions occur. Sea urchins were raised from larvae in the lab and grown from settlement for 15 weeks. This cohort was divided into two groups of equal number and size distribution, and randomly assigned to control and treatment groups. The treatment was subjected to five bouts of low salinity (21‰) for 36 hours every two weeks. As expected, at the end of the acclimation period, the treatment group was significantly smaller than the control. A 2 × 2 factorial ANOVA design was used to establish these samples in a field experiment with site and treatment level as factors in a sea urchin lease-site in the Piscataqua River, New Hampshire. Growth and survival were monitored for one year and the results show no difference in survival, but showed a significant effect of conditioning on growth. Future efforts to establish seeding programs using hatchery-reared juveniles would benefit from incorporating salinity-conditioning prior to release.

IMPROVED CULTURE TECHNIQUE FOR EDIBLE SEA URCHINS, *STRONGYLOCENTROTUS INTERMEDIUS* LARVAE. Yuichi Sakai¹, Yasuko Konda¹, Saburoh Yanagisawa², Hiroyuki Abe², Tsutomu Nishimura², Mitsutake Omoteya² and Makoto Azumi². ¹Hokkaido Institution of Mariculture, 539-112 Honbetsu, Shikabe, Hokkaido, 041-1404, Japan, ²Hokkaido Aquaculture Promotion Corporation, 4th floor, Hokkaido Dai-2 Suisan Bldg., Kita-3, Nishi-7, Chuo-Ku, Sapporo, Hokkaido, 060-0003, Japan.

The artificial mass production technique for *Strongylocentrotus intermedius* developed in 1985 allowed the production of 6.1 million juveniles in 2002, in the region of Hokkaido, Japan. However, many problems still persist particularly during the larval stage, such as mass mortality (39–100%) as measured the sinking of larvae in early 6 and 8 arms stages and the precarious settlement rate (39–98%). Other problem is the necessity for daily cleaning of

the larval rearing tank. To reduce these problems, increase in the aeration volume and food availability by temporal stop of water flow (8 hours) was attempted. To study the settlement rate, a new criterion was developed to judge the timing of larvae settlement. With the improved technique, the survival and settlement rate increased 1.7 times and 1.1 times, respectively. With this, the total amount of larval food (*Chaetoceros gracilis*) reduced and the daily cleaning of the rearing tank could be stopped, thus, reducing the load in hatchery operation. The cost of juvenile production reduced by about 10%.

POSSIBLE WAYS TO PREVENT *CRASSOSTREA GIGAS* OYSTER SUMMER MORTALITY IN FRANCE. Jean François Samain, Pierre Boudry, Lionel Degremont, Patrick Soletchnik, Michel Ropert, Edouard Bédier, Joseph Mazurié, Jean L. Martin, Jeanne Moal, Michel Mathieu, Stéphane Pouvreau, Christophe Lambert, Jean M. Escoubas, Jean L. Nicolas, Frédérique Le Roux, Tristan Renault, Thierry Burgeot and Cédric Bacher. Ifremer, Brest Center, BP 70, 29280 Plouzané, France.

A first understanding of the complex interactions between oyster, environment and pathogens was obtained during the MOREST (2001–2005) project on summer mortality events of *Crassostrea gigas* oysters in France. High trophic conditions control reproduction intensity and the susceptibility to bacterial infection. However the risk begins when temperatures exceed 19°C, mainly when an additional stressor, proximity to sediment is present. This varied between years and runoff from watersheds is implicated. Finally, a genetic resistance exists among some natural oyster populations. None of these different factors can separately account for summer mortality, and all of these conditions seem necessary to reproduce the event.

In the present case study of *C. gigas* oyster summer mortality, these necessary interactions provide different possibilities to prevent or reduce the problem by breaking one of them. Short term and long term options of reducing risk will be presented and discussed. Short term options include culture practices (temperature, trophic conditions, sediment distance, density, rearing steps, reduction of reproduction and stress). Options can depend also on biological material, with possibility of using triploids. Long term options by genetic selection of resistant oysters or by management of nutrients and organic matter from river watersheds are also possibilities. A risk analysis is necessary for each growing area to adapt the best strategy to the local environmental and culture conditions. The assessment of the economical aspects will be necessary before validation of these choices. This case study presents synergistic activities of scientists and resource managers in enhancing or restoring oyster populations in France.

A HISTOLOGICAL INVESTIGATION OF OYSTER PARASITES AND PATHOLOGY IN CHINA. Emily Scarpa, Susan Ford, Ximing Guo, Lisa Ragone Calvo and David Bushek. Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Avenue, Port Norris, New Jersey 08349 USA.

The proposed introduction of *Crassostrea ariakensis* into Chesapeake Bay as a means to restore oyster populations presents a number of potential risks, such as pathogens and pathological conditions that require careful examination and research before approval. Parasites occurring, even at low prevalence, in *C. ariakensis* within its native distribution may seriously impact this or other species in a different environment. Pathogens present in oyster species coexisting with *C. ariakensis* in its native habitat may also present problems if they are able to use *C. ariakensis* as a host or reservoir. In this survey, 27 samples were collected from eight provinces along China's coastline. Cross-sections of individual oysters were preserved in Davidson's fixative. Genetic analysis of ethanol preserved gill samples was conducted to identify species of individual oysters. Nine samples were selected based on presence of *C. ariakensis*. These oysters, representing six sites and consisting of *C. ariakensis* and a number of coexisting species, were processed by normal histological procedures and examined. Individual *C. ariakensis* were also examined using a fluorescence immunostaining technique to identify presence of *Perkinsus* sp. infections. Observed parasites included ciliates, such as *Sphenophrya*-like ciliates and trichodinids; crustaceans, including intestinal copepods; coccidians, including *Nematopsis* and a coccidian-like organism; rickettsia/chlamydia-like organisms; and trematodes. Overall prevalence of any particular parasite did not reach above 3% and averaged less than 1%. However, prevalences of coccidian-like and *Nematopsis* species were as high as 45% and 64%, respectively, at specific sites. To date, no evidence of a significant pathological impact has been observed.

AN INVESTIGATION OF CILIATE XENOMAS IN *CRASSOSTREA VIRGINICA*. Emily Scarpa¹, Susan Ford¹, Bruce Smith² and David Bushek¹. ¹Haskin Shellfish Research Laboratory, Rutgers, The State University of New Jersey, 6959 Miller Avenue, Port Norris, NJ 08349 USA, ²New Hampshire Fish & Game, Durham, NH 03824.

Since the late 1990s, unusually high prevalences of xenomas have been noted during routine histological examination of oysters from Great Bay, New Hampshire. Xenomas are formed when intracellular parasites accumulate within host cells, causing them to hypertrophy. Although in fish xenomas are commonly caused by microsporidians, in oysters xenomas are caused by ciliates, genus *Sphenophrya*, and are rare. Because they are macroscopically visible on gills, the marketability of infected oysters has been questioned. In this study, samples were collected every fall from 1997 through 2005 and processed using normal histological procedures.

In 2005, counts were also made of macroscopically visible xenomas. Prevalence varied according to site within Great Bay and also by year. In histological sections, it has increased notably since 1997, when only 1% of oysters were affected. In 2004, prevalence ranged from 33% to 82% between sites. Densities were mostly below 20 xenomas per histological section, but reached as high as 173. Macroscopically, samples from 2005 contained a mean 15.5 xenomas per oyster, ranging from zero to more than 100. The xenomas were located in gill water tubes and were often large enough to occupy the entire cross sectional area. They cause localized epithelial erosion and most likely impede water flow. Nevertheless, the histological appearance of the remaining tissues was not obviously affected and there was no clear correlation between oyster size and infection. There was an inverse relationship between the prevalence of *Haplosporidium nelsoni* (MSX) infections and that of xenomas, although the reason is presently unclear.

GONAD PRODUCTIVITY, COLOR AND TEXTURE IN *STRONGYLOCENTROTUS FRANCISCANUS* FED THREE PREPARED DIETS. Susan C. Schlosser¹, A. L. Lawrence², S. A. Watts³, P. D. Tom⁴ and J. M. Lawrence⁵. ¹University of California Sea Grant Program, Eureka, CA, ²Texas A & M University, Port Hansen, TX, ³University of Alabama, Birmingham, AL, ⁴University of California, Davis, ⁵University of South Florida, Orlando, FL.

Commercial sized *Strongylocentrotus franciscanus* (mean size 104.2 mm TD, 434.4 g) were collected from fishing grounds. An initial sample was dissected immediately. The remainder were placed individually in 25 l aquaria (n = 8/treatment) and fed one of three prepared diets. The fourth group was unfed. Dry body compartment indices, daily dry feed intake, gonad color, hardness, and resilience were measured after 60 days. A group of processed, Grade A gonads were compared with laboratory gonads. Results were compared by One Way ANOVA. There were no significant differences for dry gonad and test index, or L (gonad lightness). Dry gut index was significantly greater in prepared Diets 2 and 3 compared to the unfed treatment. Dry lantern index of the unfed group was significantly lower than the initial sample and all prepared diet treatments. Gonad redness (a) was significantly greater in the initial sample than the unfed group. Gonad yellowness (b) was significantly greater in the commercially processed gonads than in prepared diets 1 and 2 and the unfed group. Hardness of commercially processed gonads was greater than Diet 1. Resilience was significantly greater in commercially processed gonads than diets 1 and 3 and the unfed treatment. Feed intake was significantly different with Diet 1 (0.45g/urchin/day) > Diet 2 (0.41) > Diet 3 (0.31). Sea urchin gonads from Diet 3 were overall most similar to processed gonads in color and texture. Diets had similar protein, fiber, and fat content.

PERKINSUS SPP. AND BONAMIA SPP. INFECTIONS IN *CRASSOSTREA ARIAKENSIS* MAINTAINED IN A FULLY CONTAINED AQUACULTURE SETTING. Eric J. Schott, José A. F. Robledo, Mohammad R. Alavi, Keiko Saito, Satoshi Tasumi, Wolf T. Pecher and Gerardo R. Vasta. COMB, UMBI, University of Maryland, 701 Pratt St., Suite 236, Baltimore, MD 21202, USA.

In the Chesapeake Bay, diseases caused by *Perkinsus marinus* and *Haplosporidium nelsoni* (Dermo and MSX, respectively) have contributed to drastic declines of populations the native oyster, *Crassostrea virginica*. The Asian oyster, *C. ariakensis*, which grows readily to market size in Dermo-endemic Chesapeake Bay waters, is being considered for introduction to restore oyster populations. While apparently tolerant to *P. marinus*, *C. ariakensis* exposed to Bay waters may reach prevalences of up to 80%, raising the possibility that it could serve as a reservoir in which the parasite could increase its virulence. A crucial question to address is whether *P. marinus* can be transmitted from *C. ariakensis* to naïve *C. virginica*. We conducted cohabitation experiments with *Perkinsus*-infected *C. ariakensis* and *Perkinsus*-free *C. virginica*. The prevalence of *Perkinsus* infection in both 'donor' and potential 'recipient' populations was assessed at 2 and 4 weeks by PCR-based methods. After four weeks, *Perkinsus* was present in *C. virginica*. A potential protozoal disease of *C. ariakensis*, *Bonamia ostraea*, has been associated with mortalities of experimental populations of *C. ariakensis* in Pamlico Sound of NC. The potential exists for *Bonamia* sp. to be present in Chesapeake Bay. We previously detected PCR amplicons indicative of *Bonamia* spp. in *C. ariakensis* reared in the Chesapeake Bay. We are conducting cohabitation studies in which *B. ostraea*-infected *Ostrea edulis* are co-cultured with *C. ariakensis* for four weeks. We are currently in the process of analyzing possible transmission using PCR-based methodologies.

THE CALIFORNIA BAREFOOT ECOLOGIST PROGRAM: A COOPERATIVE STOCK ASSESSMENT MODEL FOR THE CALIFORNIA RED SEA URCHIN FISHERY. Steve Schroeter¹, John Duffy² and Peter Halmay³. ¹Marine Science Institute, University of California, Santa Barbara, Santa Barbara, CA 93106, ²California Department of Fish and Game, ³311103 Hwy 67, Lakeside, CA 92040.

The red sea urchin fishery in California is currently managed by a combination of size limits, seasonal and area closures, and a restricted access program. This resource is largely assessed through fishery dependent measures (i.e. landings summarized in 10 nm × 10 nm blocks and port samples of size distributions of catches) and a small number of projects that have gathered fishery independent data. Recent ecological work indicates that fishery

dependent measures are not up to the task of stock assessment and that work in the fishery independent realm does not adequately take into account the meta-population structure or the extreme spatial patchiness of the resource. This shortcoming is due in large part to the logistical requirements dictated by a resource with extreme spatial patchiness at scales ranging from 10s to 1000s of meters. We discuss a possible solution which involves the design and implementation of a cooperative stock assessment model using fishermen trained as 'Barefoot ecologists' to collect data. We describe how fishermen collect data both on the harvest grounds during routine fishing operations, and using the same sampling design, at sites outside the harvest grounds, thus providing a comprehensive fishery independent assessment of the red sea urchin stocks. We use field data to illustrate the sampling problems and to present two possible solutions we have developed to address them.

MOLECULAR MARKERS FOR PARENTAGE ASSIGNMENT IN HARD CLAM (*MERCENARIA MERCENARIA*) STOCKS. Gail P. Scott¹, Mark D. Camara², Kelly R. Johnson¹, Ryan B. Carnegie¹, Standish K. Allen Jr.¹ and Kimberly S. Reece¹. ¹VIMS, The College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062, ²USDA-ARS, OSU-Hatfield Marine Science Station.

The hard clam, *Mercenaria mercenaria*, is currently the most important aquaculture species on the east coast of the United States, yet development of selected clam brood stock is still very much in its infancy. An efficient breeding program that maximizes selection intensity, while maintaining genetic diversity, could result in substantial benefits to the industry. Selective breeding in molluscs, however, is complicated by their high fecundity and high variance in reproductive success, which rapidly can result in inbreeding. Because larval molluscs are impossible to physically tag or mark individually, one of the only practical methods of controlling inbreeding is to rear families separately; however, this requires enormous amounts of labor in both the hatchery and field. In addition, separately reared families must be replicated extensively to randomize environmental effects. Alternatively, using molecular genetic markers, families can be mixed for rearing, desired traits can be measured, and individuals can be retrospectively assigned to families based on multi-locus genotypes. We have recently developed both microsatellite and single nucleotide polymorphism (SNP) markers in *M. mercenaria*. Male and female individuals from hatchery strains originating in different regions were used as parents in controlled laboratory spawns to produce 50 distinct full-sib families. Parental tissue and larvae from each of the 50 crosses were preserved to provide progeny samples with independently known parentage for testing the power of the markers for accuracy at pedigree reconstruction.

INTRODUCTION OF THE EUROPEAN SEA URCHIN (*PARACENTROTUS LIVIDUS*) IN A LAND BASED INTEGRATED SYSTEM IN ISRAEL. Muki Shpigel and Ingrid Lupatsch. National Center for Mariculture, Eilat, Israel.

The sea urchin, *Paracentrotus lividus*, was introduced as a candidate species in a fish, seaweed and sea urchin integrated system in Eilat, Israel. While fish represent the main product, effluents from fish culture support the growth of the macroalgae, *Ulva lactuca* and *Gracilaria conferta*. Both seaweeds were used as a biofilter to remove dissolved nutrients from the water and as food for the sea urchins. Sea urchin performances in parameters such as growth, survival, food conversion ratio (FCR), protein and energy use, gonad production, and gonad color were evaluated. Growth from spawning to commercial size (45 mm) on the seaweed diet took ca 36 months, FCR on a wet weight basis ranged between five and seven, and survival rates from settlement were 70–80%. Three months before harvest, prepared diets are introduced in order to improve raw growth.

POLYCULTURE OF THE SHRIMP *LITOPENAEUS VANNAMEI* AND THE SEA URCHIN *LYTECHINUS VARIEGATUS*. Anthony J. Siccardi III¹, Addison L. Lawrence¹ and Stephen A. Watts². ¹Texas A&M University System, Port Aransas, Texas, ²University of Alabama, Birmingham, Alabama.

Polycultures potential has been researched for many species as it represents a potential cost savings to aquaculturists. This study examines the feasibility of *L. vannamei* and *L. variegatus* polyculture. Ninety-six 19-L tanks connected to a semi-closed recirculating seawater system were stocked with one *L. vannamei*. Each tank contained two elevated mesh cages to which 0, 2, or four sea urchins/tank were added. Sea urchins were fed ca. 0.3 grams of a 27% protein research feed per day per urchin. Treatments (N = 16) were: 1) two urchins per tank plus 0.2 grams per day of a supplemental commercial 45% protein shrimp feed, 2) two urchins per tank with no supplemental shrimp feeding, 3) four urchins per tank with no supplemental shrimp feeding, 4) zero urchins per tank with 0.2 grams per day shrimp feed, 5) zero urchins per tank with 0.4 grams per day shrimp feed and 6) zero urchins per tank and no supplemental shrimp feeding. Weight gain was similar in shrimp who consumed fecal material from 4 sea urchins to those fed 0.2 grams per day shrimp feed ($P > 0.05$). Weight gain was higher in shrimp who consumed fecal material from two urchins plus 0.2 grams per day of supplemental shrimp feed, and was equivalent to shrimp fed 0.4 grams per day shrimp feed ($P > 0.05$). Fecal material alone from two urchins was not able to sustain shrimp growth. Data indicates *L. vannamei* is able to utilize sea urchin fecal material which enhances the likelihood of successful commercial polyculture.

MOLTING AND CHANGES IN BODY COMPOSITION OF THE PACIFIC WHITE SHRIMP, *LITOPENAEUS VANNAMEI*, DURING STARVATION. Anthony J. Siccardi¹, William H. Neill², Addison L. Lawrence³, Delbert M. Gatlin III², Frank L. Castille¹ and Joe M. Fox⁴. ¹Texas A&M University System, Port Aransas, Texas, ²Texas A&M University, College Station, Texas, ³Texas A&M University System, Port Aransas, Texas, ⁴Texas A&M University, Corpus Christi, Texas.

Starvation studies using the comparative slaughter method contribute to better understanding of animal bioenergetics. To assess compensatory growth, researchers typically starve animals for brief periods. Few studies of shrimp or other crustaceans have assessed changes in body composition upon starvation over periods as long as one month. To determine the effect of long-term starvation, four weight classes (initially weighing 5.51, 7.19, 14.10, and 16.59 g per shrimp) of *L. vannamei* were individually held without feeding in 400 tanks (100 shrimp and tanks per size class). Ten shrimp were removed weekly, weighed and then individually analyzed for energy, ash, moisture and protein until mortality was complete. Shrimp continued to molt throughout the study, despite the energy loss and stress involved in the molting process. The daily loss of protein per shrimp was described by the following equation: protein loss ($\text{g shrimp}^{-1} \text{ day}^{-1}$) = $0.0045 * W(\text{g})^{0.92}$, where W = geometric mean of body weight between the initial and final weights after 28 days of starvation. Daily loss of energy was described as energy loss ($\text{cal shrimp}^{-1} \text{ day}^{-1}$) = $37.15 * W(\text{g})^{0.87}$. Molting reduced the volume of the starved 5.51 g shrimp by approximately 34%. A reduction in volume also was noted for *L. vannamei* fed below their maintenance protein and energy requirements. The authors believe this loss of volume reflects a tendency toward homeostatic maintenance of tissue water and energy density requisite for functional integrity.

LONG-TERM STUDY OF FEED INTAKE AND GROWTH UNDER CONSTANT TEMPERATURE REGIME IN THE GREEN SEA URCHIN (*STRONGYLOCENTROTUS DROBACHIENSIS*). Sten I. Siikavuopio, Trine Dale and Bjørnsteinar Sæther, Norwegian Institute of Fisheries and Aquaculture Research, Fiskeriforskning, 9291 Tromsø, Norway.

A long-term study of feed intake, somatic growth and gonad growth of green sea urchin, *Strongylocentrotus droebachiensis* was conducted. Three size groups of sea urchins (initial diameter: 35 mm (S), 45 mm (M) and 50 mm (L)) were held individually in square chambers for 850 days and fed *ad libitum* a formulated moist feed. The animals were kept at constant water temperature (10°C) and under simulated natural photoperiod regime. Feed intake (FI), feed conversion efficiency (FCE), somatic growth, gonad index (%) and gonad colour were measured. The feed intake in all size groups seemed related season, as the feed intake was significantly higher in summer compared to winter. The multiple linear regression show that the somatic growth curves of different

size groups had significantly different slopes ($P < 0.05$) ($S = 37.472 + 0.025x$, $M = 44.447 + 0.019x$, $L = 52.286 + 0.01x$, where x = days). S group had the fastest increase in test growth ($P < 0.05$), followed by size group M, and L. There were no significant differences in gonad index, FCR and gonad colour between the groups at the end of the experiment. Overall, our finding suggest that the feeding rates of the adult green sea urchins show a strong correlation with season, possibly due to the annual reproduction cycle.

OSCILLATIONS IN SEA URCHIN POPULATIONS ALONG THE NORWEGIAN COAST. Knut Sivertsen, Finnmark University College, Alta, Norway.

Barren grounds appeared from kelp beds along the Norwegian coast caused by heavy grazing by the sea urchins (*Strongylocentrotus droebachiensis*) during the 1970s and 1980s. In the 1990s kelp re-established in the southern part after the sea urchin populations had declined. No increase of predators or no parasite infection in the sea urchins was registered in the re-established areas. A hypothesis is proposed that differences in population dynamics of the sea urchins may explain for this pattern. In the southern area mortality and individual growth rates may be higher than in the northern area because of highest temperature in the south. A higher growth rate may cause a shorter life length in the south than in the north. Then a higher and more regular recruitment is needed to stabilize a population in the south. If the population decreases to under critical breeding level, there is a greater chance for the sea urchin population to break down. A bet-hedging life history strategy is previously proposed for sea urchins. Bet-hedging, explained shortly, means that populations sometimes rapidly increase to a high level, but afterwards the density gradually decreases. This strategy is here discussed in the light of different stages of the life table and regional differences in the water temperature. Each parts of the life cycle should be analysed to find if the mortality at any of the stages is sensitive to fluctuations. High longevity of a species may compensate for high variability in recruitment.

A REVIEW OF QPX DISEASE EMPHASIZING INITIATION AND PROGRESSION. Roxanna Smolowitz, Marine Biological Laboratory, 7 MBL St., Woods Hole, MA 02536.

QPX was reported by Drinnan and Henderson in hard clams from Canada in 1960. In 1995, QPX was diagnosed in cultured hard clams in Provincetown and Duxbury, MA. QPX has since been identified in clams from Virginia, New Jersey, New York and Rhode Island waters, as well as other locations in Massachusetts. It continues to cause marked mortality in MA and RI. QPX organisms primarily invade through the mantle at the base of the siphon. Studies have demonstrated direct infection of naive clams three months after exposure to infected dying clams, but not when exposed to cultured QPX via the water column. Infection location

in 100% of those clams occurred at the siphon base and in the adjacent mantle. In other work, seed clams examined six months after planting showed disease in 33% of the population and the primary infection site, identified histologically, was at the base of the siphon. QPX organisms were noted amid debris in the mantle cavity at the base of the retracted siphon (pseudofeces location). These findings indicate residence time in that location, perhaps as part of pseudofeces, is important in the pathogenesis of the disease. Quizzically, prevalence of QPX disease appears to vary greatly with some plots showing high prevalence in one clam population followed by low prevalence in a replacement population, or some plots repeatedly showing high prevalence of the disease even in replacement populations. Studies show disease prevalence at any single time period may not accurately indicate previous or future disease prevalence.

GENETIC IDENTIFICATION AND PHYLOGENY OF THE UNIONID GENERA, *LAMPSILIS* AND *ELLIPTIO* OF THE SOUTH EAST ATLANTIC SLOPE. Kristine M. Sommer, Ami E. Wilbur and Michael A. McCartney. University of North Carolina, Department of Biology and Marine Science, 601 S. College Road, Wilmington, NC 28403.

Approximately 70% of freshwater mussel species in North America are considered extinct, endangered, or threatened, and a large number of these are endemic to a narrow geographic range. Freshwater mussel conservation efforts have been limited by taxonomic ambiguities and morphologic convergence. Lake Waccamaw in southeastern North Carolina contains two described endemic species, *Lampsilis fullerkati* and *Elliptio waccamawensis*, which conchologically are nearly identical, complicating conservation efforts. To help alleviate this problem, a Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP) assay was developed for genetic identification. Genomic DNA was obtained using a non-lethal method of hemolymph extraction. Two diagnostic RFLPs were used to type 112 individuals. RFLP and sequencing data showed that three individuals were misidentified based on morphology. In addition, phylogenetic analysis was used to assess the taxonomic status of these putative endemics. 16S ribosomal DNA sequences were obtained from 140 individuals from both genera, sampled from Lake Waccamaw, the adjacent Waccamaw River, and the Yadkin/Pee Dee and Lumber Rivers in the Pee Dee Drainage. Results from neighbor-joining and maximum likelihood trees suggest the endemic status of both *L. fullerkati* and *E. waccamawensis* may need to be reconsidered. *Lampsilis fullerkati* individuals fall in a large clade containing *Lampsilis radiata radiata* from outside the lake, and the endemic is not a distinct phylogroup. Additional, faster-evolving gene regions and type specimens are being sequenced to evaluate this result. A similar approach is being used for *E. waccamawensis*, which appears phylogenetically indistinguishable from *Elliptio* collected outside of the Lake.

INFLUENCE OF CLIMATIC CYCLES ON THE INFECTION OF EASTERN OYSTERS BY *PERKINSUS MARINUS*.

Thomas M. Soniat¹, John M. Klinck², Eric N. Powell³ and Eileen E. Hofmann². ¹Department of Biology, Nicholls State University, ²Center for Coastal Physical Oceanography, Old Dominion University, ³Haskin Shellfish Research Laboratory, Rutgers University.

Perkinsus (= *Dermocystidium*) *marinus* is a major cause of mortalities in eastern oysters, *Crassostrea virginica*. Since initiation of infection and progression of disease are favored by high temperature and high salinity, we hypothesized that climatic cycles influence cycles of disease. Using wavelet analysis and a 10-year data set of disease prevalence and intensity, and water temperature and salinity from a Louisiana site, we show a teleconnection between the El Niño Southern Oscillation and oyster disease in the northern Gulf of Mexico. Inter-annual variation is important in the initiation and intensification of disease, and salinity is the primary driving factor. An increase in salinity is followed in several months by an increase in prevalence followed in several months by an increase in infection intensity, with salinity shifts strongly driven by ENSO events. The time series suggests that epizootics can be initiated within six months of a La Niña event, during which high water temperature and high salinity coincide. This relationship makes it possible to anticipate epizootics of *P. marinus* from climate models and to better manage oyster populations.

DERMOWATCH DETECTS DISEASE HOTSPOTS IN THE GULF OF MEXICO.

Thomas M. Soniat¹, Sammy M. Ray², Enrique Kortright³ and Lance Robinson⁴. ¹Department of Biology, Nicholls State University, ²Department of Marine Biology, Texas A&M University, Galveston, ³Kortright Corporation, ⁴Texas Parks and Wildlife Department.

DermoWatch (www.dermowatch.org) is a web-based community for the monitoring and management of the lethal oyster parasite, *Perkinsus marinus* (= *Dermocystidium marinum*). Oysters from the major oyster producing areas of the Gulf of Mexico are collected and assayed for *P. marinus*. The web site displays station information, water temperature and salinity, and percent infection and disease intensity (weighted incidence) of sub-market and market-sized oysters. Weighted incidence values of 2.0 and greater are highlighted as "hotspots", where oysters (*Crassostrea virginica*) are likely experiencing serious disease-related mortality. Recent disease hotspots are found in Corpus Christi Bay, Aransas Bay, Matagorda Bay and Galveston Bay. Within a bay, hotspots are established on high-salinity reefs and proceed up-estuary. Between bays, hotspots tend to progress from south to north. Within and between bay patterns of progression and regression of disease hotspots are likely cyclical, and should provide a useful indicator of the trajectory of infection.

INFLUENCE OF OYSTER REEF VERTICAL COMPLEXITY IN STRUCTURING SPECIES SPECIFIC INTERACTIONS AND TROPHIC LINKAGES. Joseph Michael Sonnier, M. H. Posey and T. D. Alphin. UNC-Wilmington, Center for Marine Science, 5600 Marvin K. Moss Lane, Wilmington, NC 28409.

Habitat complexity is important in regulating trophic linkages, with broad implications for community composition. Habitat complexity can alter species interactions through impacts on refuge and food. High and low complexity oyster reefs in southeastern North Carolina provide an ideal system to test these ideas. Interactions between bivalve prey (oysters and mussels) and predators (mud crabs) may be affected by the presence of vertical complexity and consequent access by larger predatory crabs. We examined the effects of oyster reef vertical complexity on mud crab populations and mud crab: bivalve interactions in the presence of a top predator, the blue crab. Mud crab density was significantly greater in areas of high vertical complexity during both field and lab studies. Lab studies indicated mud crab predation on bivalve (oyster spat and mussels) prey was greater in high complexity oyster patches, but consumption of mussels was greater than consumption of spat for all trials. In trials containing the top predator, predation by mud crabs was reduced, especially in the low complexity patches where predation approached zero. Field studies show oyster spat recruitment to be higher on newly created low complexity reefs. Tethering trials indicate predation on mud crabs increased as oyster reef complexity decreased with open sand having the highest predation. However, an edge effect was detected for high complexity reefs, with highest predation on mud crabs located within five cm of the edge. Reef complexity in this system may have limited top predator access, affecting mud crab: bivalve predator-prey dynamics.

THE FEASIBILITY OF USING TRIPLOID *CRASSOSTREA VIRGINICA* FOR ON BOTTOM CULTURE IN THE CHESAPEAKE BAY. Melissa Southworth¹, Roger Mann¹, Thomas Leggett Jr² and A. Erskine³. ¹Virginia Institute of Marine Science, P.O. Box 1346, Gloucester Point, VA 23062, ²Chesapeake Bay Foundation, ³Cowart Seafood Company and Bevan's Oyster Company.

The Federal Register, Vol. 69, No. 2, dated Monday, January 5, 2004 provided notice of "DEPARTMENT OF DEFENSE, Department of the Army; Corps of Engineers Intent [To Prepare a Programmatic Environmental Impact Statement] for the Proposed Introduction of the Oyster Species, *Crassostrea ariakensis*, Into the Tidal Waters of Maryland and Virginia To Establish a Naturalized, Reproducing, and Self-Sustaining Population of This Oyster Species," and described seven alternatives to be evaluated in the EIS process. Alternative 4 addressed the issue of using the native oyster (*Crassostrea virginica*) species in the development and expansion of aquaculture in the Chesapeake Bay. In the past, the ma-

jority of Virginia's commercial oyster production came from leased oyster ground. Historically, lease holders would either purchase or harvest oyster seed from rivers such as the Great Wicomico, Piankatank or James, and plant on their leases throughout the Virginia portion of the Bay. We describe a project to examine the feasibility of using triploid native spat on shell in the same manner as oyster planters have used wild oyster seed from seed Rivers. Approximately forty million triploid larvae were set on 400 bushels of shell and planted on an oyster bed owned by Bevan's Oyster Company in the Yeocomico River, Virginia in summer 2005. We present here early results of setting success, growth, mortality and condition index.

COMMUNITY ECOLOGY OF FRESHWATER MUSSEL BEDS: THE ROLE OF TEMPERATURE AND DOMINANT SPECIES ON COMMUNITY STRUCTURE AND RENDERED ECOLOGICAL SERVICES. Daniel E. Spooner and Caryn C. Vaughn, University of Oklahoma.

Recent work suggests that freshwater mussel beds significantly influence stream ecosystem function through benthic-pelagic coupling of energy and nutrients. Mussel communities comprise a mosaic of species that differ in their species-specific thermal performance. These performance curves influence resource acquisition, potentially shaping community structure (species dominance) and subsequent ecological function. We traveled to 21 mussel beds across southeastern Oklahoma and western Arkansas. We quantified community structure (time-search and quadrats), physiological condition (glycogen, body condition index (BCI), and measures of rendered services (metabolism, nutrient excretion). We predicted that species would be dominant at sites that closely resemble their empirically derived thermal performance optima. Our results to date suggest that communities are alternately dominated by two species *Actinonaias ligamentina* and *Amblema plicata*. Both species co-occur, have opposing thermal performance trajectories, and are negatively correlated within sites. In addition, condition and performance indices of co-occurring mussel species was related to species richness, *A. ligamentina*, and *A. plicata* biomass. These results suggest that species interactions including facilitation/competition may be important factors explaining community structure and subsequent ecological services rendered by freshwater mussel beds.

OVIERY IN THE SPOT SHRIMP (*PANDALUS PLATYCEROS*) OF HOOD CANAL. David A. Sterritt, Washington Department of Fish and Wildlife.

Egg numbers and seasonal trends in ovigery of were established for Spot shrimp (*Pandalus platyceros*) from Hood Canal during testfisheries conducted during the 2003–2005 season. Ovigerous shrimp were found to be smaller in size and had fewer

eggs than Spot shrimp sampled in other investigations. A linear relation was found between egg number and carapace length.

EMBRYONIC DEVELOPMENT AND MORPHOMETRY OF BLUE KING CRAB *PARALITHODES PLATYPUS*, STUDIED BY IMAGE ANALYSIS. Bradley G. Stevens, NMFS/NOAA Kodiak Fisheries Research Center.

Embryonic development has been described for few commercial crab species, and no standard exists for defining developmental stages. I examined the embryonic development of the blue king crab, *Paralithodes platypus*, from the Pribilof Islands in the eastern Bering Sea. Fertilized embryos were digitally photographed at various intervals throughout their development using a compound microscope and measured with an image analysis program. Seven morphometric parameters were measured (total area, yolk area, embryo length and width, average diameter, eye length and width) and four indices were calculated (percent yolk, ellipticity, elongation, and circularity). First divisions occurred on day four, after which divisions occurred daily until the blastopore appeared at day 28. A "V"-shaped embryo became apparent on day 114, and the eyes became pigmented by day 192. Hatching occurred from day 381 to day 409, and required at least 33 days. Embryo area declined from 0.95 mm² on day 1 to 0.83 mm² on day 72, and then increased to 1.28 mm² on day 388. Developmental stages were defined visually and by using cluster analysis of embryo measurements. Both methods resulted in an optimum selection of 12 stages. Visual methods were better at defining early changes, but morphometric measurements were better at defining middle and later stages. Morphometric analysis techniques may lead to improved understanding of crustacean embryogenesis and effects of environmental change, and have applications in the aquaculture industry.

PRELIMINARY ANALYSES OF GENETIC STRUCTURE WITHIN AND AMONG REMNANT POPULATIONS OF THE OLYMPIA OYSTER, *OSTREA CONCHAPHILA*. David A. Stick¹, Heather Hunsperger², Chris Langdon¹, Michael A. Banks¹ and Mark D. Camara³. ¹Oregon State University, COMES, HMSC, 2030 SE Marine Science Dr., Newport, OR 97365. ²Eckerd College, St. Petersburg, FL. ³USDA-ARS, HMSC, Newport, OR.

The Olympia oyster, *Ostrea conchaphila*, is the only oyster species native to the Pacific Northwest. Historically, the species ranged from Southeastern Alaska to Baja, California, Mexico and supported both Tribal subsistence fisheries and large commercial harvests. Over-exploitation, habitat degradation, and competition and predation from non-native species have drastically depleted densities and reduced the overall range, but remnant populations persist. Due to the species' historical significance and the ecological services provided by oyster reef habitats, numerous restoration

efforts are proceeding without a full understanding of existing population structure, which may be complicated due to *O. conchaphila*'s larviparous mode of reproduction and limited larval dispersal as well as extensive population admixture due to human mediated translocations. Identifying appropriate broodstock and maintaining the genetic integrity of populations is essential for the long-term success of restoration efforts, but conducting population-level studies have been hindered by a lack of molecular markers. We have developed a number of microsatellite DNA markers in *O. conchaphila* and conducted preliminary analyses of genetic structure. We first constructed several microsatellite enriched genomic libraries then isolated and sequenced individual clones from them. We next designed primers to the flanking regions of confirmed microsatellites, optimized PCR conditions and verified Mendelian segregation in larvae from five hatchery-produced full sib families. Polymorphism was assayed using a panel of 96 oysters from eight locations, and the most polymorphic markers were used for preliminary analyses of broad-scale patterns of genetic diversity and differentiation within and among populations ranging from northern Vancouver Island, BC to San Francisco Bay, CA.

IMPACTS OF OYSTER REEF ARCHITECTURE ON SPECIES DIVERSITY AND PREDATION. Jennifer L. Stiner and Linda J. Walters, University of Central Florida.

Widely regarded as a keystone species and ecosystem engineer, the eastern oyster, *Crassostrea virginica*, plays a vital role in estuarine environments. Complex three-dimensional oyster reefs act as biodiversity havens. Recently, concern for this resource has arisen in Mosquito Lagoon, Florida. Since the 1990s, intense boating activity has caused atypical dead margins (mounds of disarticulated shells) to emerge on the seaward edges of oyster reefs located along major boating channels. Once dead margins are formed, little is known about their influence on biotic composition and interactions. This study focused on the impact of dead margins on (1) species diversity and (2) predation. For one year, monthly surveys were conducted using lift nets to document all mobile species present on reefs in Mosquito Lagoon. Sixty-four species were recorded, including fishes, crustaceans, molluscs, echinoderms, and worms. Mini lift net trials revealed species diversity to be highest on fore-reef and back-reef areas, with drastic reductions on dead margins of impacted reefs. Field experiments were conducted to determine the impact of dead margins on the vulnerability of juvenile oysters. Structural variables (e.g. shell orientation, single versus clumped shells, and overall slope) were manipulated and effects were observed on oyster mortality and predator maneuverability. Responses of three major predators (*Callinectes sapidus*, *Urosalpinx cinerea*, and *Panopeus herbstii*) differed. For *C. sapidus* and *P. herbstii*, predation was higher on disarticulated shells while *U. cinerea* showed a preference for spat on clumped shells. Overall, this study documents ecological implications of dead margins on reefs of *C. virginica*.

VARIATION IN OYSTER SHELL STRENGTH BASED ON STOCK ORIGIN, SHELL SIZE AND TRANSPLANT EFFECT. Heather Stoker, Troy Alphin and Martin Posey. University of North Carolina, Center for Marine Science, 5600 Marvin K. Moss Ln., Wilmington, NC 28409.

This study compares the breaking strength of *Crassostrea virginica* shells from four Southeastern North Carolina estuarine systems: New River, Cape Fear River, Stump Sound and White Oak River. Shell strength comparisons were made among three size classes within each estuary and among estuaries for oysters in one size class (40–50 mm). Five oysters per size class per estuary (120 oysters total) were selected. As morphological differences may suggest variation in mechanical properties, the length, width, muscle scar thickness and weight of each shell were recorded. An eleven-millimeter disc was cut from the muscle scar of the right valve of each specimen. The discs were strength tested using an Instron 8511 material testing machine, measuring compressive break strength (MN/m²). The oysters used in this project were from a previous study on stock differentiation; therefore, shell strength can be compared to existing data on the oysters' growth, survival, stock type and estuarine conditions. If the intrinsic strength of *C. virginica* shells differs among origin or transplant location, this has implications of potential differences in predation risk and susceptibility to disease.

POPULATION STRUCTURE AND PHYLOGEOGRAPHY OF THE PINTO ABALONE (*HALIOTIS KAMTSCHATKANA*) IN WASHINGTON STATE. Kristi Straus, Kerry Naish and Carolyn Friedman. University of Washington, School of Aquatic & Fishery Sciences, P.O. Box 355020, Seattle, WA 98195.

The Pinto abalone (*Haliotis kamtschatkana*) is the predominant haliotid species in Washington State and is an ecologically important herbivore in rocky subtidal habitats. Although the Washington abalone fishery was closed in 1994, abundance and population densities have declined dramatically since this time. In order to enact an effective conservation strategy, it is imperative to determine the population structure of the Pinto abalone. Previous microsatellite studies indicated low differentiation among Pinto abalone collections in British Columbia, Canada. However, our research on genetic variation at microsatellite loci in over 100 individuals from Washington State revealed substantial population structure. All microsatellite loci exhibited significant deviations from Hardy Weinberg expectations (positive F_{IS}) and linkage disequilibrium was evident between most pairs of loci. Using MtDNA sequence analysis, ten individuals from S.E. Alaska (U.S.), British Columbia (Canada), and Washington State (U.S.), and five individuals from California (U.S.) were sequenced at the Cytochrome Oxidase B locus (Cyt B, 404 bp). Results from this locus indicate that although animals from Alaska, B.C. and California appear to be closely related, six of the ten Washington individuals sequenced

diverge strongly. These six individuals share four haplotypes unique to Washington State. These same six individuals were sequenced at Cytochrome Oxidase I (COI, 343 bp). At COI, these six individuals share three unique haplotypes relative to sequence available on Genbank. Further studies are needed to elucidate the biological significance of the observed genetic differences. These findings have significant implications for the listing and restoration of abalone found in Washington State.

GENETIC ISSUES IN FLORIDA HARD CLAM AQUACULTURE. Leslie Sturmer¹, Charles Adams², Patrick Baker², Shirley Baker², Elise Hoover², Claudia Rocha² and John Scarpa³. ¹Cooperative Extension Service, University of Florida, Cedar Key, FL 32625; ²Institute of Food and Agricultural Sciences, University of Florida, Gainesville, FL 32611; ³Harbor Branch Oceanographic Institution, Ft. Pierce, FL 34946.

The hatchery-based hard clam aquaculture industry in Florida, while rapidly growing, is in its infancy in terms of stock management and improvement. A concern in the loss of useful genetic variation through unintentional inbreeding was addressed by developing an index of clam stock health. Using mitochondrial DNA and microsatellite loci in the nuclear genome, genetic diversity in captive strains from multiple Florida hatchery stocks was quantified and compared to wild stocks. Hatchery stocks were cultured simultaneously during 2004–5 to compare performance under aquaculture conditions and correlate with genetic diversity. The need for a hardier clam strain also became evident as Florida culturists reported below average survivals during hot summers. The project team is currently evaluating triploidy as a means to improve stress resistance by reducing gametogenesis and increasing body mass. Triplicate groups of sibling diploid and triploid hard clams were planted under commercial conditions on leases to compare production characteristics. Responses of clams subjected to laboratory environmental challenges (high water temperatures and low dissolved oxygen levels) are being evaluated to determine the physiological mechanism by which triploidy may improve survival in subtropical waters. Finally, the economics of triploid seed production and triploid clam culture will be characterized.

A SURVEY OF MARINE COMMUNITIES IN ALTERNATIVE CULTURE METHOD OYSTER AND CLAM SITES. Andrew D. Suhrbier¹, Daniel P. Cheney¹ and Jonathan P. Davis². ¹Pacific Shellfish Institute, 120 State Ave. NE #142, Olympia, WA 98501. ²Baywater Inc.

The past two decades have seen a rapid expansion of alternative and innovative methods for the cultivation of oysters and hardshell clams; however, there is limited information on the interactions of these practices with the surrounding environment. As part of a larger project, multi-season sampling was conducted to 1) assess and compare benthic infauna and epifauna species diversity and

density, across habitat types within culture and control sites; to 2) assess responses of infauna and epifauna to culture conditions; and to 3) monitor and compare selected macrofauna including juvenile salmon, shrimp and crabs, across habitat types. Methods evaluated included bag-on-rack, bag on bottom, and suspended bag culture of oysters and bag on bottom and net-protected ground culture of manila clams. Discussed will be the results of seasonal benthic collections, net deployments and underwater video footage at each survey site. Survey sites included commercial shellfish farms in Thorndyke Bay, Hood Canal and Eld Inlet, in South Puget Sound, Washington. This project was funded by the SeaGrant National Marine Aquaculture Initiative.

CONNECTICUT'S HARD CLAM INDUSTRY AND QPX-DISEASE. Inke Sunila, State of CT, Department of Agriculture, Bureau of Agriculture.

Connecticut, on Long Island Sound's north shore, is the leading producer of hard clams, *Mercenaria mercenaria*, with a yearly production of over 400,000 bushels and a yearly farm gate value of over \$10 million. Since 1997, the year of a major *Haplosporidium nelsoni* (MSX) epizootic among oysters, production has been rising steadily. After that harvesters concentrated on the hard clam fishery. Hard clam aquaculture is practiced on over 65,000 acres of leased grounds. Recruitment originates mostly from natural set and harvest size clams are collected by hydraulic dredges and transplanted onto approved grounds for depurification prior to marketing. The health of CT's clams has been monitored annually since 1997. QPX was detected in six out of 2358 clams (0.3%) from 77 different samples along the shoreline. None of the QPX-positive clams originated from commercial clam grounds. Two positive clams were collected from natural oyster beds during culching. Three positive clams were collected next to shipping channels. One of the clams originated from a bed of false quahogs, *Pitar morrhuana*, being surveyed as a potential future hard clam site. Sampling sites for the positive clams are distributed along the entire CT shoreline: Bridgeport, Stratford, New Haven and Groton. Histopathologically affected clams have mucus producing, proliferating presentation of QPX-disease. However, QPX is not currently considered to pose a threat to CT's hard clam industry.

THE LOUISIANA OYSTER RECOVERY PLAN: A RESPONSE TO HURRICANES KATRINA AND RITA. John Supan¹ and Mike Voisin². ¹Louisiana Sea Grant College Program, LSU, Baton Rouge, LA 70803, ²Louisiana Oyster Task Force, Motivait Seafood, Inc.

Hurricane Katrina caused unprecedented damage to the central gulf coast, being the greatest natural disaster in U.S. history. The paths of Hurricanes Katrina and Rita passed through major Louisiana oyster production areas, causing between 55–70% oyster mortality to the public grounds by scouring and overburden, with

likely similar damage to private farms yet to be determined. Infrastructure and fleet damage to public agencies and the private sector were also severe. The Louisiana Oyster Task Force, legislatively mandated to guide the state in the management and development of its oyster industry, is enacting a recovery plan to address five areas of need: (1) vessel and lock recovery; (2) harvest areas, (3) dock and unloading facilities, (4) processing plants, and (5) market development. This multi-faceted approach challenges all involved to new paradigms. Some of the components include: refloating some 1,800 commercial fishing vessels aground by storm surges; continued and additional microbiological sampling to open more harvest areas; developing dockside refrigeration program; cultch placement on public and private oyster grounds; opening and closing oyster seasons on public oyster grounds by location and specific dates; lifting current moratorium on new oyster farm lands; rebuilding and improve the Sea Grant oyster hatchery on Grand Isle and initiate a Louisiana Oyster Seed Program focusing on genetically superior stocks; developing off-bottom culture in designated marine enterprise zones and/or aquaculture parks; and, postponing 2005 lease rental payments until 2006.

BIOCHEMICAL COMPOSITION AND ADDUCTOR MUSCLE CELL SIZE OF TRIPLOID AND DIPLOID BAY SCALLOP *ARGOPECTEN IRRADIANS*. Amandine Surier¹, Chester B. Zarnoch² and Richard C. Karney¹. ¹Martha's Vineyard Shellfish Group, P.O. Box 1552, Oak Bluffs, MA 02557, ²AREAC, Brooklyn College, Brooklyn NY 11210.

Triploidy, which has been found to improve overall performance in many shellfish, is particularly interesting in scallops as the increased growth rate is associated with decreased gonad development and increased adductor muscle mass. Triploid's increase in somatic biomass is thought to be the result of energy reallocation from reproduction towards somatic growth or increased fitness due to higher heterozygosity. Another hypothesis is triploidy gigantism, which associates the increased size of triploid organisms with a larger cell size. In July 2003, under funding from the Northeastern Regional Aquaculture Center, triploidy was induced in the bay scallop *Argopecten irradians*. The experimental scallops, which tested 97% triploid in July 2004, were grown in bottom cages in Katama Bay, Massachusetts. Triploid wet adductor muscle indexes were 52% and 17% greater than diploids in July and October 2003 respectively.

In December 2004, triploid and diploid adductor muscle samples were sent to Brooklyn College for biochemical composition. Although the protein and carbohydrate contents were higher and lipid content was lower in triploid muscles the differences were not significant. In the spring 2005, survivors from the experiment were sampled for cell size analysis. A portion of the smooth adductor muscle from triploids and diploids was processed using standard histological techniques, photographed and analyzed

for muscle cell size and number of cells/area using NIH ImageJ software. Adductor smooth muscle fibers of triploids were significantly wider than those of diploid controls. In contrast, the number of muscle fibers per unit area was not significantly different between ploidy groups.

EFFECTS OF PREDATION AND SETTLEMENT SUBSTRATE CHOICE ON THE POST-SETTLEMENT SURVIVAL OF RED ABALONE, *HALIOTIS RUFESCENS*. Clara Svedlund¹, Steven Gaines¹, Jennifer Caselle¹ and Laura Rogers-Bennett². ¹Ecology, Evolution and Marine Biology, U. C. Santa Barbara, ²California Department of Fish and Game & Bodega Marine Lab.

Historically abundant populations of abalone (*Haliotis* spp.) are now at drastically reduced levels throughout Southern California. Two particularly vulnerable stages in the life cycle of these broadcast spawning invertebrates are the larval and post-settlement stages. Laboratory studies of predation on cultured veliger larvae and newly settled red abalone (*Haliotis rufescens*) indicate that predation may be an extremely important source of mortality at these stages. Results from predation experiments revealed that important predators of *H. rufescens* include the crabs *Pagurus* sp., *Cancer* sp., and *Scyra* sp., the terebellid *Eupolytnia* sp., and the sea urchin *Strongylocentrotus purpuratus*. Ninety-seven percent of all predators tested were sources of mortality for settling or settled abalone, whether due to consumption, bulldozing, or other modes. Settlement experiments using three categories of encrusting red algae (ERA) indicated that substrate type may play a larger role in the survival and subsequent growth of settled larvae. Compared to the two other types, settlement and post-settlement survival was significantly higher for the category of crustose coralline algae (CCA) with an irregular surface (e.g. *Lithothamnium pacificum*). Further experiments that tested the interaction of substrate (the three ERA types) and predation (using two different predators) revealed that the more rugose substrate again conferred the highest survival. This higher survival may be due to the morphology of the CCA, which might provide abalone with predation refugia and/or superior grazing sources. Potential larval/post-larval seeding experiments may benefit from selection of sites with a higher cover of the rugose encrusting corallines, and exclusion of probable predators.

ANNUAL VS. NONANNUAL EGG EXTRUSION, MATING VS. UTILIZATION OF STORED SPERM, AND LARVAL HATCHING OF KODIAK, ALASKA DUNGENESS CRAB. Katherine M. Swiney, NOAA Fisheries, Alaska Fisheries Science Center.

Previous studies report nonannual egg extrusion among Dungeness crab in southeastern Alaska, which differs from the annual egg extrusion typically reported for Dungeness crab. Dungeness

crab from Kodiak, Alaska waters were reared in flow-through tanks to determine if egg extrusion is annual and to observe which crab mate or utilize stored sperm to fertilize egg clutches. Females were collected from two bays on the eastside of Kodiak Island May through August 2005, a time in which females should either have eggs or recently hatched larvae. Thirty one percent of females collected did not have eggs the previous reproductive season. Seventy one percent of females brought into the laboratory used stored sperm to fertilize eggs while 26% molted/mated. Females that molted/mated were significantly smaller than females that did not molt. As of 12, December 2005, 52% of females extruded eggs in two consecutive years, whereas 28% skipped at least one reproductive season and extruded an egg clutch the following season; more extrusion is expected. Larval hatching was examined in 2004 with females brought into the laboratory a week before hatching, which began at the end of May and lasted 25 days. Individually, larval hatching ranged from 8 to 16 days with a mean of 11 days. Larger crab took significantly longer to hatch larvae and had significantly more larvae. Egg extrusion is not annual for all mature Dungeness crab collected from Kodiak waters, however, preliminary evidence suggests more crab may extrude eggs annually in the Kodiak area than in southeastern Alaska.

CAROTENOIDS IN THE SEA URCHIN *PARACENTROTUS LIVIDUS*. Rachael Symonds and Andrew Young, Liverpool John Moores University, School of Biological and Earth Sciences, Byron St., Liverpool UK.

The roe of the edible sea urchin *Paracentrotus lividus* is commercially valuable and highly prized in the sushi market. However, roe colour varies with season, the urchin's nutritional state, its state of maturity and its sex. This study has characterised the carotenoid pigment profile of the gonads and gut wall of wild *P. lividus* using a combination of reversed-phase diode-array HPLC and LC-MS. The major pigments occurring in the gut wall are breakdown products of fucoxanthin, namely fucoxanthinol and amarouciaxanthin A. Lower levels of echinenone, lutein, isozeaxanthin and β -carotene are also present. The gut wall of the female urchins contains pigments not present in the males, indicating additional metabolism in the former. It is clear that the gut wall is a major site of carotenoid metabolism. Male and female gonads have a broadly similar pigment profile with echinenone accounting for between 70–80% of the total carotenoid (c.f. gut: 20%). Both all-*trans* and 9'-*cis* forms of β -echinenone are found in the ratio 1:10 (w/w). The detection of large levels of 9'-*cis*-echinenone in wild *P. lividus* is unexpected due to the absence of 9'-*cis* forms of carotenoid in the natural, algal, diet. Amounts of lutein and isozeaxanthin are consistently higher in the female rather than male gonads with levels of these peaking shortly after spawning. The presence of 9'-*cis* echinenone as the major carotenoid contributing to the pigmentation/colour of the gonad is an important observation in terms

of developing artificial diets for urchin cultivation. The implications of this are discussed further.

EELGRASS RESPONDS TO OYSTERS AND GROW-OUT METHODS IN AN AQUACULTURE SETTING. Heather Tallis¹, Jennifer Ruesink¹, Brett Dumbauld², Sally Hacker³ and Lorena Wischert³. ¹University of Washington, ²Hatfield Marine Science Center, ³Oregon State University.

Aquaculture has been shown to have negative impacts on eelgrass and certain aquaculture practices have been banned in the Pacific Northwest (USA) to protect eelgrass as valuable habitat. We argue that the magnitude of tradeoffs between aquaculture and biodiversity depends on the ecological details of the production system. We explored three aquaculture systems (dredged on-bottom, hand picked on-bottom, long lines) to quantify the tradeoffs between oyster (*Crassostrea gigas*) aquaculture and eelgrass (*Zostera marina*) habitat. Capitalizing on large scale “manipulations” for aquaculture in Willapa Bay, WA, we found lower eelgrass density in all aquaculture systems relative to uncultivated areas in 2002–2004. Dredged beds had the lowest eelgrass densities (~50% < uncultivated) while hand picked and long line beds were intermediate. After experimental dredging, eelgrass densities recovered in one to four years, depending on site and disturbance intensity. Additionally, eelgrass density declined with oyster density in cultivated beds, although oysters were sparsely planted (~20% cover). Eelgrass growth ($\text{g g}^{-1} \text{d}^{-1}$), measured in 2004, also varied by aquaculture type and oyster density, although patterns in this individual-level indicator were context-specific. Total above-ground production was largely driven by variation in eelgrass density, so dredged beds had the lowest production. Our findings do not support regulations against all on-bottom aquaculture because hand picked beds showed the least tradeoff in terms of eelgrass production and were 1.5–2.3 times more productive than dredged beds. We suggest several management options that may allow the continued co-existence of aquaculture and eelgrass in the Pacific Northwest.

SETTLEMENT OF *CRASSOSTREA ARIAKENSIS* LARVAE UNDER CONDITIONS FOUND IN THE CHESAPEAKE BAY. Mario N. Tamburr¹, Mark W. Luckenbach², Denise L. Breithurg³ and Stephanie M. Bonniwell⁴. ¹Chesapeake Biological Laboratory/UMCES, ²Virginia Institute of Marine Science, ³Smithsonian Environmental Research Center, ⁴Virginia Institute of Marine Science.

The Asian oyster (*Crassostrea ariakensis*) is being considered for introduction into the Chesapeake Bay. However, our current understanding of the biology and ecology of *C. ariakensis* is insufficient to predict whether an introduction will be successful,

provide desired benefits, or have adverse impacts. Behavior of native oyster (*C. virginica*) pediveligers has been studied for many years and it is well established that they use a variety of habitat characteristics when selecting a site for colonization. Perhaps the most important of these are chemical cues emitted by adult conspecifics, which can lead to gregarious larval settlement and dense, persistent reef communities. Conversely, almost nothing is known about how larvae of *C. ariakensis* respond to conditions found in Chesapeake Bay or about the critical life history processes of settlement and metamorphosis. We have examined how the behavior and substrate preference of two *C. ariakensis* strains (“south China” and “west coast”) at the time of settlement compares with that of *C. virginica*. Results demonstrate many similarities but also a few important differences. For example, both species and strains of larvae greatly prefer natural substrates (e.g. shell) covered with biofilms for colonization but the west coast strain of *C. ariakensis* exhibited greater attachment onto manmade substrates (e.g. fiberglass) than *C. virginica*. Waterborne chemical cues emitted by adult oysters were also found to enhance substrate attachment for all larval forms, whereas initial data suggests hypoxia inhibits larval attachment with the south China strain of *C. ariakensis* perhaps most sensitive to low oxygen conditions.

ASSESSMENT OF RED ABALONE, *HALIOTIS RUFESCENS*, POPULATIONS AT SAN MIGUEL ISLAND, CALIFORNIA. Ian K. Taniguchi and Peter L. Haaker, California Department of Fish & Game.

San Miguel Island contains the southernmost large population of red abalone, *Haliotis rufescens*, along the Pacific coast, but commercial and recreational abalone fishing was closed in 1997 because of a general decline. Since then, red abalone size frequency has improved at San Miguel Island and at some surrounding locations. The California Fish and Game Commission have recently adopted an Abalone Recovery and Management Plan, which includes a provision for reopening a commercial and recreational fishery at San Miguel Island. To address the potential fishery, an assessment of the abalone resources will need to be completed. Diving surveys, using 2×30 m band transects to collect density and size frequency data, are optimized using stratification of suitable abalone habitat at San Miguel Island within one nautical mile square ($1 \text{ min} \times 1 \text{ min}$) grids. Maps of giant kelp, *Macrocystis pyrifera*, beds are used as a surrogate for hard benthic abalone habitat, and are overlain on the one mile square grids in a geographic information system. Within the common grid-kelp areas, thirty points are randomly selected for diving surveys. Data will be used to determine red abalone size frequency and density for management, and compared to historic size frequency data. It will also provide comparisons between areas in and out side of recently established marine protected areas.

EVIDENCE OF A RESPONSE TO UNINTENTIONAL SELECTION FOR FASTER DEVELOPMENT ASSOCIATED WITH INBREEDING DEPRESSION IN *C. GIGAS*. Nicolas Taris¹, Frederico M. Batista², Eric Marissal¹ and Pierre Boudry¹. ¹INFREMER-LGP, Station de la Tremblade, La Tremblade, France. ²INIAP/IPIMAR, Olhão, Portugal. ³Grainocéan, St Martin de Ré, France.

Direct and indirect consequences of selective breeding in marine bivalves still remain largely unexplored. For species with two-phase life cycles, like the Pacific oyster (*Crassostrea gigas*), most studies have focused on juvenile and adult stages, but relatively few have considered the larval stage, especially in a domestication context. We assessed the impact of hatchery practices on larval traits, notably on larval growth (due to the culling of slow growing larvae), by the study of larval progenies. Larvae originating from crosses using parental oysters both from natural beds and from hatchery broodstock which had been selected for adult growth and shell shape for seven generations. A set of three microsatellite loci was used to compare genetic variability in the two parental broodstocks and to establish the relatedness between pairs of individuals within each broodstock. The mean relatedness was nearly six times higher in the hatchery broodstock than in the wild broodstock. On one hand, our results show a lower mean survival associated with larger variation of growth rate showing a bimodal distribution for the hatchery larval population. On the other hand, a higher success at metamorphosis was observed for the surviving larvae bred from hatchery parents. The results suggest that some of these larvae exhibited inbreeding depression but this was balanced by an overall positive response to selective pressures for larval growth.

EVALUATION OF SUSPENDED ADPI® BAGS VS. BOTTOM PLANTING FOR USE AS BAY SCALLOP SPawner SANCTUARIES. Stephen T. Tettelbach, Andrew Weinstock, Dennis Bonal, Chelsea Fitzsimons-Diaz, Richard Ames and Katherine Newman. Southampton College of Long Island University, 720 Northern Blvd., Brookville, NY 11548.

An off-bottom culture system for bay scallops (*Argopecten irradians irradians*), employing stacks of 15 mm mesh ADPI® bags (= arrays), was compared to bottom (free) planting as an alternate method for establishing spawner sanctuaries. Two stocks of hatchery-reared scallops were separately overwintered and then deployed at one site in Northwest Harbor, East Hampton, NY in ADPI arrays (50, 100, or 200 scallops/bag = 117, 234, or 468 scallops/m², respectively) or free-planted at a mean density of ~95 scallops/m² on 30 March to 1 April 2005. In all, 12,600 scallops were stocked into ADPI arrays and ~235,000 scallops were free-planted. Overall survival, to late September 2005, of free-planted scallops (~31%) was better than that of scallops in ADPI bags (~18%). Cumulative mortality increased gradually in both scallop groups over the course of the study. Shell growth, from an initial mean stocking size of 38–40 mm, was significantly greater in free-planted scallops compared to those held in arrays ($t = 7.10$;

$p < .0001$). The timing of spawning, as determined via biweekly monitoring of gonad indexes, was similar in both groups of scallops. After 4.5 months, biomass of epifaunal fouling organisms on free-planted scallops (mean = 0.88 g whole wet weight per scallop) was lower than that on scallops held in ADPI bags (mean = 3.78 g whole wet weight per scallop). A second field season in 2006 will be used to evaluate a modified version of the initial ADPI array system.

VARIABILITY OF PHYTOPLANKTON BIOMASS IN THE DAMARISCOTTA RIVER ESTUARY. Brian Thompson, Mary Jane Perry¹ and Christopher Davis². ¹University of Maine, Darling Marine Center, 193 Clark's Cove Road, Walpole, ME 04573. ²Pemaquid Oyster Company, P.O. Box 302, 1957 Friendship Road, Waldoboro, ME 04572.

Phytoplankton biomass and environmental parameters in the Damariscotta River Estuary, Maine, USA, were quantified over space and time to better assess the carrying capacity of this prime location for shellfish mariculture. Water samples were collected two to five times a week between February and October 2005 at three stations in the estuary—mouth, middle, and head—and analyzed for chlorophyll *a* and phaeopigment concentrations, dissolved inorganic nutrients, temperature, and salinity, with less frequent collection for phytoplankton taxonomic identification. In summer, additional locations were sampled from a small boat and with moorings. Stations between the middle and head of the estuary were occupied over two separate fortnightly tidal cycles between July and September; moored instruments were deployed from late August to early September. Photosynthetically available radiation was continuously recorded at the middle station at the Darling Marine Center dock. An offshore mooring, GoMOOS Buoy E, provided additional data to assess external forcing on the estuary. In 2005, the late winter phytoplankton bloom at the middle station was delayed and significantly smaller in both magnitude and duration in comparison to blooms in the previous two winters. Nitrate concentrations were highest at the beginning and end of the year, with a significant draw down of all nutrients concurrent with the late winter bloom. Chlorophyll concentrations were typically highest at locations in the upper estuary. Identification of regions with persistent occurrence of high phytoplankton biomass throughout the growing season are important to oyster farmers for determining locations for culturing.

GENETIC AND ECOLOGICAL INTERACTIONS IN A MUSSEL HYBRID ZONE. R. J. Thompson, D. J. Innes, J. B. Lowen and M. B. Miranda. Ocean Sciences Centre, Memorial University of Newfoundland.

Understanding the processes that maintain the coexistence of closely related species requires studies of life-history variation, competition and hybridization. *Mytilus edulis* and *M. trossulus* coexist and hybridize throughout Atlantic Canada. Nuclear and mtDNA genetic markers have shown that F_1 hybrids are very rare

(<1% of the population) but individuals of mixed genotype (backcrosses) account for about 25%. Larvae and small mussels are predominantly *M. trossulus* or hybrids whereas larger mussels are almost exclusively *M. edulis*. A cohort analysis of laboratory-produced mussels of known species composition transplanted to the field showed that *M. edulis* grew faster and had a greater survival rate than *M. trossulus* or hybrids. A detailed analysis of energy allocation to soft tissues and shell demonstrated that *M. trossulus* had a greater investment in reproductive tissue and a lower investment in shell mass than *M. edulis*. Hybrids had an intermediate allocation pattern. A lower investment in shell mass, adductor muscle mass and byssus production resulted in a greater susceptibility of *M. trossulus* to crab and starfish predation. Life-history trade-offs involving reproduction, growth and survival are probably instrumental in explaining the coexistence of *M. edulis* and *M. trossulus*. Furthermore, a combination of reduced interspecific fertilization success (prezygotic) and post-fertilization mortality (postzygotic) results in partial reproductive isolation, which can explain the observed frequency of hybrids.

MULTI-VARIATE ANALYSIS OF SPATIAL VARIABILITY OF OYSTER-REEF COMMUNITIES: THE INFLUENCE OF SALINITY. S. Gregory Tolley, Aswani K. Volety, Mike Savarese, Christi M. Linardich, Laura D. Walls and Edwin M. Everham III. Florida Gulf Coast University, Coastal Watershed Institute, 10501 FGCU Blvd. South, Ft. Myers, FL 33965.

When assessing oyster-reef habitat in estuaries, it is important to understand the contribution of salinity to the spatial variability of associated organisms. How comparable is community structure among stations located along the salinity gradient of an estuary or among tidal tributaries experiencing different levels of freshwater inflow? To address these questions, multi-variate techniques were employed to analyze decapod crustacean and fish abundance data. Organisms were collected at three reefs along the salinity gradient (upper, middle, lower) of three estuaries: Caloosahatchee River, Estero River and Bay, and Faka Union Canal and Bay. Additional collections were made in Estero Bay from oyster reefs located at the mouths of five tidal tributaries. Cluster analysis did not reveal any natural groupings by estuary. Analysis of similarity did reveal significant differences among sites along the salinity gradients within estuaries and between Estero Bay tributaries. Multi-dimensional scaling identified community structure present at upper stations as distinct from that downstream, and at high-flow tributaries as distinct from that near low-flow tributaries. Upper stations and stations near high-flow tributaries were typified by the mud crab, *Eurypanopeus depressus*, and gobiid fishes. Downstream stations and stations near low-flow tributaries were typified by *E. depressus* and the porcelain crab, *Petrolisthes armatus*. Percent dissimilarity was greatest when upper and lower stations were compared or when high-flow and low-flow stations were compared. Variability in multivariate structure tended to be higher

upstream or in association with high-flow tidal tributaries, a pattern suggesting that freshwater inflow is disturbing communities at these locations.

CAN HEAT SHOCK PROTEIN 70 EXPRESSION BE USED AS A BIOMARKER FOR ENVIRONMENTAL STRESS IN THE EASTERN OYSTER? Nobuo Ueda and A. A. Boettcher. University of South Alabama, LSCB 124, Mobile, AL 36688.

Significant declines in eastern oyster, *Crassostrea virginica*, populations have occurred along the coasts of the eastern United States and Gulf of Mexico. Anthropogenic disturbances are thought to be the main cause of these declines, with changes in abiotic environmental conditions, either in conjunction with, or independent of these anthropogenic factors contributing to increased mortality in specific areas. Understanding the responses of oysters to environmental stressors and developing simple tools for detecting their effects is critical for the successful monitoring of oyster populations. As a part of the Alabama Oyster Reef Restoration Program, we have been examining the usefulness of heat shock protein 70 (HSP 70) expression as a biomarker of environmental stress in *C. virginica*. As has been shown with other oyster species, three isoforms of HSP 70, two constitutive (77 and 72 kDa) and one inducible (69 kDa), have been identified in the eastern oyster, *C. virginica*. However, it is not known how different environmental stresses impact the expression of these three isoforms. This study examined differences in expression of HSP70 isoforms in *C. virginica* based on both type of environmental stress (salinity, temperature, and dissolved oxygen) and age of the oyster. Levels of environmental stress, type of stress, and age of the oyster all impact HSP 70 expression, with differences in the expression levels among isoforms of HSP 70 associated with the different factors. Clarifying how these factors interact will allow for a better evaluation of the effectiveness of HSP 70 as a biomarker.

PROTANDRY, MATURATION, AND SPAWNING IN CULTURED INTERTIDAL GEODUCK (*PANOPEA ABRUPTA*) CLAMS. Brent Vadopalas¹, Cyrus S. Y. Ma¹, Jonathan P. Davis² and Carolyn S. Friedman¹. University of Washington School of Aquatic and Fishery Science, 1122 NE Boat St., Seattle, WA 98105. ²Baywater, Inc.

Among the challenges facing aquaculture of endemic species are potential negative effects of gene flow from cultured to wild populations. Solutions include maturation control, monosex outplants, spatial or temporal separation, and harvest before sexual maturation. To assess whether cultured intertidal geoduck clams mature and spawn before harvest, we sampled 12 geoduck ten times over the course of one year (2004–2005) from each of five year classes (1999–2003) planted conterminously in south Puget Sound, Washington. Additional sampling occurred through a second spawning season from the 2001, 2002, and 2003 year classes. Individuals were sexed, weighed, and measured; histological sections of gonad were classified by developmental stage (early ac-

tive, late active, ripe, partially spawned, spent). Using image analysis, we calculated a gonadal-somatic index for each individual. Of geoducks age 1.5–2.2 years, approximately 23% exhibited evidence of spawning and 71% were mature, compared to 68% and 89% respectively in geoducks age 4.5–5.0 years. We estimate that 50% maturation occurs at 64 mm shell length at this site. Male:female ratios in two to five year old geoducks were male-biased relative to the predominate 1:1 sex ratios observed in wild populations ($p < 0.05$), providing evidence of facultative protandric dioecy. Maturation stage in cultured geoducks was temporally correlated with maturation stage in wild populations, indicating no temporal separation. Taken together, these data suggest that (1) pre-maturation harvest to prevent gene flow may be untenable and (2) future efforts be directed toward exploring the viability of maturation control in this species.

USING QUANTITATIVE PCR AND DNA BARCODES TO QUANTIFY AND IDENTIFY MARINE INVERTEBRATE LARVAE. Brent Vadopalas, Joshua V. Bouma, Chemine R. Jackels and Carolyn S. Friedman. University of Washington School of Aquatic and Fishery Science, 1122 NE Boat St., Seattle, WA 98115.

Information on the relationship between behavior and dispersion in marine invertebrate larvae has been hampered by the lack of suitably rapid techniques for identification and quantification from field samples. The need to understand larval dispersal dynamics of the pinto abalone (*Haliotis kamtschatkana*), which was recently listed as a species of concern (U.S.) and threatened (Canada), motivated the development of a high-throughput method for identification and quantification of abalone larvae in seawater samples. Seawater was filtered through a 70 μ m screen and DNA was extracted from all organisms present in sample retentate. Species-specific Cytochrome Oxidase I (COI) mitochondrial DNA sequence was used as template for Quantitative PCRs (QPCR) containing primers and a dual-labeled hydrolysis probe. Direct enumeration of larvae using light microscopy was used to verify quantity estimates derived from QPCR standard curves. To avoid bias from either underestimation of quantity or false negatives, abalone-specific reactions were multiplexed with primers, probe and exogenous template as an internal positive control (IPC) to indicate partial or full PCR inhibition. Differences between direct counts ($n = 1$ –141) and QPCR estimates were not significant, and the average coefficient of variation was 0.56 for within-run replicates, indicative of high accuracy and precision. We estimate that 80 samples can be processed from DNA extraction through QPCR in about four hours at a cost of approximately \$2/sample. Our results demonstrate that QPCR may have high utility for high throughput identification and quantification of specific marine invertebrate larvae in seawater samples via counts of mtDNA COI “barcodes” using constructed standard curves.

POPULATION STRUCTURE IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA* ASSESSED BY SINGLE NUCLEOTIDE POLYMORPHISMS. Robin L. Varney and Patrick Gaffney, University of Delaware, Smith Lab, 700 Pilot-town Rd., Lewes, DE 19958.

Single nucleotide polymorphisms (SNPs) are abundantly distributed throughout plant and animal genomes. Because the number of loci is virtually unlimited and they are amenable to robust high-throughput genotyping, SNPs are rapidly becoming standard tools for the analysis of population structure, genetic mapping, and taxonomic identification. Our goal is to evaluate population structure of the eastern oyster throughout its range from Atlantic Canada to the Yucatan Peninsula, using a large number of SNPs identified in known genes (Type I SNPs). While previous work has shown a clear genetic break between Atlantic and Gulf coast populations in mitochondrial DNA, studies of geographic variation in nuclear loci (allozymes and anonymous DNA markers) have yielded mixed results. Existing genomic and expressed sequence tag (EST) databases of *C. virginica* have been mined for the development of both anonymous and type I markers, with recent efforts focused on genes thought to be involved in disease response. Direct sequencing of amplified targets has revealed extensive polymorphism in *C. virginica*. We have developed a set of nuclear SNP markers to examine the genetic diversity of *C. virginica* throughout the species range and provide multiple markers for genetic linkage mapping. Significant heterogeneity in allelic frequencies among the geographic locations was observed for each locus. Our results are consistent with the Gulf-Atlantic split previously observed with other markers. In addition, clinal patterns in allelic frequencies in Atlantic populations are suggested for some loci.

ASSESSING IMPACTS OF SHELLFISH AQUACULTURE ON EELGRASS POPULATIONS IN EASTERN LONG ISLAND SOUND. Jamie Vaudrey¹, Tessa Getchis² and Bob Britton². ¹University of Connecticut, Department of Marine Sciences, 1080 Shennecossett Road, Groton, CT 06340. ²University of Connecticut, Connecticut SeaGrant, 1080 Shennecossett Road, Groton, CT 06340.

Eelgrass (*Zostera marina*) is the dominant vascular plant of northern estuaries of the east and west coasts of the United States. Eelgrass beds provide critical ecological functions such as removing nutrients and stabilizing fine sediments. Beds also provide critical habitat to a myriad of marine organisms including juvenile fish, shellfish, and crustaceans, among others. Eelgrass is on the decline in most estuaries, coincident with urbanization and the resulting increase in nutrient loads to the coastal waters. The presence of eelgrass is considered an indicator of a “healthy” system and much attention has been focused on investigating potential causes of the loss of eelgrass and determining methods to minimize the decline in eelgrass abundance. Bivalve aquaculture, specifically the utilization of submerged cultivation and depuration

gear such as cages, has been implicated as a potential source of negative impacts to eelgrass populations. However, shellfish aquaculture gear has also been shown to provide an equivalent or greater degree of ecosystem services as submerged aquatic vegetation such as eelgrass. This study was conducted to determine the type and degree of impacts and benefits that oyster depuration bottom cages have on eelgrass and surrounding water and sediment quality, in order to provide producers and policy-makers with the scientific data needed to make informed decisions regarding the siting of aquaculture in Long Island Sound. Preliminary results suggest an increase in eelgrass growth rate, measured as sheath length. No treatment effect was seen for water column properties, sediment % organics, or benthic microalgae concentrations.

FRESHWATER MUSSELS: SPECIES ROLES, ECOSYSTEM SERVICES AND CONSERVATION. Caryn C. Vaughn, Daniel E. Spooner and Heather S. Galbraith. Oklahoma Biological Survey and Department of Zoology, University of Oklahoma, Norman, OK 73019.

Our lab is using an integrative approach of comparative field observations, field experiments, and laboratory experiments to address three fundamental questions concerning freshwater mussel guild: (1) What is the importance of the mussel guild to stream ecosystem function?; (2) Do species perform different ecological roles?; and (3) Do species roles vary with environmental context? Our results indicate that many ecosystem services performed by mussels (algal clearance, nutrient excretion, biodeposition) are linearly related to community biomass; thus, there is the potential for strong ecosystem effects when mussel biomass is high and hydrologic residence times are long. Algal growth is higher on the shells of living mussels compared to shells alone, and macroinvertebrate richness and densities are higher on the shells of living mussels and in mussel patches than in other streambed areas. Field and laboratory experiments demonstrate strong effects of a potential driver species, *Actinonaias ligamentina*, on factors such as periphyton biomass, but comparatively weak diversity effects. In addition, species effects are context-dependent and regulated by abiotic factors such as temperature and flow. Our results indicate that some mussel species are performing differently in streams and are thus not redundant, but that performance and potential redundancy are context dependent. Using an extensive dataset on mussel community composition and biomass from across southeastern Oklahoma and western Arkansas, we are scaling up our results to make predictions about mussel contributions to ecosystem services in natural streams and how this may vary as the environment changes.

MANAGING A DUNGENESS CRAB (*CANCER MAGISTER*) FISHERY FOR MULTIPLE USER GROUPS: THE PUGET SOUND, WASHINGTON, EXPERIENCE. Lisa Veneroso and Richard Childers. Washington Department of Fish and Wildlife.

Intensive fishery management strategies have been adopted for Dungeness crab (*Cancer magister*) in Puget Sound, Washington, in response to increases in fishing pressure. In 1994, a U. S. Dis-

trict Court decision ruled treaty Indian tribes in Washington State have the legal right to harvest up to 50% of shellfish, including Dungeness crab, in their usual and accustomed fishing grounds. Prior to 1995, Dungeness crab were harvested exclusively by a state commercial and recreational fishery using a passive "3S" harvest strategy of minimum size, set season, and sex (male crab only). The guiding assumption of the 3S strategy being that male crab > 6 1/4 inches are surplus and can be harvested at a high rate and not threaten reproductive success or the sustainability of the resource. Since 1995, crab harvest has increased from three million to eight million pounds, harvest seasons have been adjusted on a regional basis to more closely adhere to molt timing, and annual pre-season quotas have been established. Currently, the fishery is managed through harvest sharing agreements that allocate harvest between 15 treaty tribes conducting predominantly commercial fisheries, a state commercial fishery consisting of 250 licenses and a recreational fishery with an estimated 200,000 anglers. Fishery managers are questioning whether the management scheme adopted for Puget Sound is sustainable considering the high exploitation rate, the handling mortality of female and sub-legal size male, and the lack of stock abundance information needed to evaluate the appropriateness of the pre-season quotas.

ENERGY STORAGE AND UTILIZATION IN RELATION TO GAMETOGENESIS OF *ARGOPECTEN VENTRICOSUS*. Janel Rogelio Villalaz Guerra, Juan A. Gomez Herrera and Luis D'Croz. Departamento de Biología Marina, University of Panama.

A laboratory study was carried out to observe changes in reproduction of *Argopecten ventricosus* by using histological techniques in gonads and chemical analysis of digestive gland, adductor muscle, mantle-gills and gonad. These data allowed us to calculate energy storage related to gametogenesis of *A. ventricosus*. During 66 days, combinations of monocultures (50:50) of C-ISO and CH-I were added daily to a tank with filtered and aerated seawater. Salinity and temperature of the water were measured with a salinity-temperature probe meter (YSI). Phytoplankton densities were recorded by direct count with a hemacytometer. This study is a contribution to the reproductive biology of *A. ventricosus* and fisheries management of the tropical scallop.

DIFFERENT TYPES OF NEOPLASIA IN *CRASSOSTREA GIGAS*, *VENUS VERRUCOSA* AND *MYTILUS GALLOPROVINCIALIS* FROM THE SPANISH COAST. Antonio Villalba, Centro de Investigaciones Mariñas, Xunta de Galicia, P.O. Box 13, 36620 Vilanova de Arousa, Spain.

New cases of neoplasia corresponding to three types of neoplastic condition are described. One out of 22 oysters, *C. gigas* taken from an oyster farming area in the Ría de Arousa (Galicia,

NW Spain) showed disseminated neoplasia (DN). Histological analysis revealed abundant abnormal cells with large (up to 5 μm) round nucleus and scant cytoplasm infiltrating the connective tissue close to the stomach and in blood sinuses, suggesting invasiveness; mitotic figures were frequent but other organs appeared free of abnormal cells, suggesting an early stage of disease. DN prevalence in oysters *Ostrea edulis* cultured in that area is high, thus the possibility of interspecies transmission should be assessed. One out of 25 warty clams *Venus verrucosa* taken from a bed close to Maó (Balearic Islands, Spain) appeared affected by another type of neoplasia. Histological analysis revealed abnormal cells with large, extremely elongated (up to 10 μm long) nucleus and scant cytoplasm replacing normal cells of the connective tissue of the visceral mass; mitotic figures were frequent and no abnormal cell was observed in blood vessels. One out of thousands of mussels *Mytilus galloprovincialis* examined in a histopathological programme ran for 10 years throughout the Galician Rías were affected by germinoma. The mussel was hermaphrodite, with some gonad follicles containing either male or female gametes and some other follicles appeared filled with highly basophilic cells, tightly packed, likely deriving from germinal epithelium of the follicles. Mitotic figures were seen in those masses but they were not frequent.

COMPARISON OF IMMUNE PARAMETERS BETWEEN OYSTER STOCKS AND SPECIES WITH DIFFERENT SUSCEPTIBILITY TO INFECTION BY *BONAMIA OSTREAE*.

Antonio Villalba, Pilar Comesaña, Sandra M Casas and Asunción Cao. Centro de Investigacións Mariñas, Xunta de Galicia, Spain.

The parasitic protozoan, *Bonamia ostreae*, causes oyster, *Ostrea edulis*, mass mortalities throughout the European Atlantic coast, whereas the allochthonous oyster, *Crassostrea gigas*, is resistant to bonamiosis. Previous studies indicated that the *O. edulis* strain "Rossmore" produced through selective breeding has increased tolerance to bonamiosis compared to other European stocks of flat oyster. The immune capability of oyster *O. edulis* stocks with different susceptibility to bonamiosis and that of oysters *C. gigas* were compared to assess whether some immune parameters could explain the differences in susceptibility to infection by *B. ostreae* between oyster stocks/species. The *O. edulis* stocks used in the comparisons were: Rossmore (selected strain), oysters from Tralee Bay (Ireland) where the parasite had not previously been detected, and oysters from natural beds in Galician Rías (Spain) that are affected by bonamiosis. The immune parameters selected for comparisons were total haemocyte count and differential haemocyte count of the haemolymph; phagocytic ability of haemocytes; intra- and extracellular production of superoxide anion, production of hydrogen peroxide and production of nitric oxide by haemocytes; antibacterial activity in haemocytes and plasma; phenoloxidase and acid phosphatase activities in haemocytes and plasma; and protease inhibitory activity in plasma.

Consistent differences in any of the immune parameters studied between *O. edulis* stocks that explained differences in susceptibility to bonamiosis were not found. However, some of the immune parameters would be candidates to explain differences in susceptibility to bonamiosis between *O. edulis* and *C. gigas*.

STOCK-RECRUIT RELATIONSHIPS FOR *CRASSOSTREA VIRGINICA* AND *C. ARIAKENSIS* IN CHESAPEAKE BAY DEVELOPED FOR A DEMOGRAPHIC OYSTER POPULATION MODEL. Jon H. Volstad and Jodi R. Dew, Versar, Inc., 9200 Rumsey Road, Columbia, MD 21045.

A demographic population model is being developed to support an ecological risk assessment (ERA) of the proposed introduction of *Crassostrea ariakensis* and restoration alternatives of *C. virginica* in Chesapeake Bay by the states of Maryland and Virginia. As part of the model, a stock-recruit relationship was developed and is defined as the ratio of number of spat recruited to October (when the annual Fall survey is performed by the Maryland Department of Natural Resources (DNR)) to number of standardized (to 77 mm) female oysters. Stock-recruit relationships were estimated using empirical data collected from 1980 to 2004 by the DNR in annual surveys of oyster beds in Maryland, shell length data, sex ratio by size estimates, and fecundity relationships between shell length and number of eggs produced. R-square value for *C. virginica* stock-recruit relationship was 0.45 with 2.6 spat produced per standardized female oyster. The number of spat produced was 2.6, 2.8, and 2.1 per standardized female oyster when the stock-recruit relationship was examined per average, dry, and wet rainfall year, respectively. This stock-recruit relationship for *C. virginica* is used for *C. ariakensis* to predict the number of spat produced per standardized *C. ariakensis* stock to a 77mm female *C. virginica* oysters, under the assumption of similar mortality rates for spat of both species to October. The stock-recruit relationship for both species can also be altered to include gamete loss from inviable hybrids in cross-fertilization when species are reproducing in close proximity to each other.

ESTIMATION OF ANNUAL MORTALITY RATES FOR EASTERN OYSTERS (*CRASSOSTREA VIRGINICA*) IN CHESAPEAKE BAY BASED ON BOX COUNTS AND APPLICATION OF THOSE RATES FOR POPULATION GROWTH PROJECTIONS. Jon H. Volstad¹, Jodi R. Dew¹ and Mitchell Tarnowski². ¹Versar, Inc., 9200 Rumsey Rd., Columbia, MD 21045. ²Maryland Department of Natural Resources.

In an effort to restore the ecological role of oysters in Chesapeake Bay and the economic benefits of a commercial fishery, the states of Maryland and Virginia are considering the introduction of

the non-native Asian oyster, *Crassostrea ariakensis*. As part of the ecological risk assessment (ERA) to evaluate the proposed action and restoration alternatives, demographic modeling is applied to project the change in populations of both Asian and eastern oyster populations in the Bay in space and time. We present two approaches to parameterize the annual mortality rates for the Asian and eastern oyster for the demographic model. Mortality rates were estimated from empirical data collected by the Maryland Department of Natural Resources (DNR) in annual surveys of oyster beds in Maryland. We compared counts of recent boxes (dead oysters including gapers about two weeks old, in which tissue is still found within the shell, as well as boxes with no fouling or sedimentation on the inner valve surfaces), old boxes (dead oysters in which fouling and/or sedimentation is found on the inner valve surfaces and no tissue remains), and live oysters in both market and small size classes. Our mortality estimates from recent box counts consistently differentiated between years with high versus low disease intensity and wet and dry years, and also between salinity zones. In contrast, traditional estimates of yearly mortality based on total box counts were often out of phase with measured disease intensity levels, and type of weather year (dry or wet).

UNDERSTANDING DIET DEVELOPMENT IN RELATIONSHIP TO SEA URCHIN GAMETOGENESIS. Charles W. Walker and S. Anne Boettger, The University of New Hampshire.

One challenge when culturing adult green sea urchins is the formulation of diets yielding palatable and marketable roe. Current commercial diet formulations vary and yield taste, color and texture variation of the product. High protein content of diets related to production of large gonads yields poor taste, while color is related to carotenoid content. Nutrient uptake into nutritive phagocytes (NPs) of the gonad (somatic cells in both sexes) is an important factor as sea urchin gonads are large before and during gametogenesis due to nutrient storage by NPs. Initially, NPs incorporate nutrients into membrane-bound vesicles in the cytoplasm and mobilize them as germ cells enlarge during gametogenesis. Mechanisms of nutrient delivery to NPs and from them to germ cells have been a focus of recent studies. At completion of oogenesis NPs contain basal amitotic oogonia and small/intermediate-sized vitellogenic primary oocytes, though their major activity is enclosure and nourishment of vitellogenic oocytes prior to maturation and release. Mechanisms regulating differential nutrient release by sea urchin NPs and their selective uptake by germ cells at different stages of gametogenesis are unknown though there is coordination between NPs and germ cells. Oocytes must be receptive to incorporate nutrients released by NPs at specific times. Endocytosis by oocytes increases two fold, uptake of MYP increases 10-fold during this time. It is inevitable that changes in nutrients delivered to germ cells may be related to the

quantity/quality or kind of food ingested by sea urchins, which has to be taken into account during diet development.

PHYSIOLOGICAL RESPONSES TO SALINITY STRESS IN THE FLATBACK MUD CRAB *EURYPANOPEUS DEPRESSUS*. Laura D. Walls and S. Gregory Tolley, Florida Gulf Coast University, Coastal Watershed Institute, 10501 FGCU Blvd. South, Ft. Myers, FL 33965.

Estuaries in Southwest Florida experience highly altered freshwater inflow resulting in part from anthropogenic activities. To gauge possible effects of altered salinity regimes on species in these systems, physiological responses to salinity stress were investigated in the flatback mud crab, *Eurypanopeus depressus*, a dominant member of oyster-reef communities in the region. Haemolymph osmolality and oxygen consumption were measured for animals acclimated to 5‰, 15‰, 25‰, and 35‰ over a period of four weeks in a laboratory setting. Haemolymph osmolality varied significantly with respect to salinity, with measured osmolalities at each salinity treatment being significantly different ($p < 0.0001$) from one another. Oxygen consumption also varied significantly with salinity, with values recorded for the lowest salinity treatment (5‰) being generally higher ($p < 0.0001$) than all other treatments over the length of the study. Oxygen consumption did not vary over the first three weeks of the study for animals acclimated to 5‰ but declined significantly by week four. This general pattern of increased oxygen consumption in response to dilute salinity levels is a trend that has been documented previously in several estuarine species. The results of this study suggest that osmoregulation requires greater energy expenditure by *E. depressus* at sub-normal salinity levels. Having to expend additional energy to meet osmoregulatory demands can result in reduced amounts of energy available for processes such as growth and reproduction, thereby affecting organism health. Suboptimal salinity levels resulting from altered freshwater inflow can thus significantly affect species abundance and distribution, specifically in the upper reaches of estuaries.

IMPACT OF WATER MOTION ASSOCIATED WITH RECREATIONAL BOATING AND HURRICANES ON INTERTIDAL OYSTER REEFS. Linda Walters¹, Paul Sacks¹, Loren Coen², M. Yvonne Bobo³, Donnia Richardson³, Melinda Donnelly⁴, Sarah Johnson⁴ and Heidi Deutsch⁴. ¹University of Central Florida, ²South Carolina Department of Natural Resources, ³South Carolina Department of Natural Resources, ⁴University of Central Florida.

In major recreational boating channels in shallow-water estuaries along the east coast of Florida, piles of disarticulated shells that extend up to one m above the high tide line on the seaward

edges of intertidal reefs of *Crassostrea virginica* are becoming more and more abundant. As part of a larger study to understand the impact of these “dead margins” on critical habitats, we addressed the following questions: 1) what is the relative importance of boat wakes versus larger-scale, naturally generated (e.g. hurricane) wakes in shaping reef profiles, 2) what is the prevalence and intensity of oysters with *Perkinsus marinus* on pristine reefs versus reefs with dead margins, and 3) what is the potential for dead margins to be colonized by native and invasive plants. We documented significant shell movement from a single boat pass by a reef, while 22 m/s winds moved less than 1% of deployed shells. Additionally, the three hurricanes in 2004 impacting this area had negligible effects on reef profiles. Likewise, no significant differences were detected for *Perkinsus* in oysters between pre- and post hurricane sampling on dead or healthy reef margins. Red mangroves produce seeds year-round in central Florida and these seeds colonized dead margins if they recruited between winter and mid-summer. Water levels were higher each fall, preventing recruitment of red or late-summer black mangrove seeds at this time. Invasive Brazilian pepper seeds dispersed each winter. Although these seeds were frequently observed on dead margins, none were retained long enough for recruitment to occur.

TO PIT OR NOT TO PIT?: COMPARISON OF OVERWINTERING METHODS FOR OYSTERS. William C. Walton¹, Ben Wright² and Diane C. Murphy³. ¹Cape Cod Cooperative Extension & Woods Hole Sea Grant, ²Cape Cod AmeriCorps, ³Cape Cod Cooperative Extension.

The threat of ice damage has forced intertidal oyster farmers to devise strategies to reduce potential losses. In New England, some oyster farmers move their oysters from the farm location to storage area, or ‘seed pit’, that is typically cold (0–4°C) and damp (over 90% relative humidity). Qualitatively, local farmers have reported survival rates of over 90%. We quantified survival and typical time to revival of oyster, (*Crassostrea virginica*) seed as a function of storage time. While survival was good and did not seem to vary over the course of the experiment, there was a clear step-wise drop in time to revival. Furthermore, a study of survival of seed held in the pits of local farmers suggested survival remained high (≥86%) for seed held for ~4 months but dropped to 82% for those held an additional month. Furthermore, evidence suggests that second year seed do not survive pitting as well as first year seed. Alternatives to pitting include leaving the oysters on the farm location or moving them to deeper water, below any ice that might form. We compared overwintering survival and growth of these three methods, both immediately post-winter and across the 2005 growing season. The lowest survival was in the treatment left on the flats, apparently due to damage from ice, while little to no growth was

observed immediately post-winter. More surprisingly, there was a tendency for growth across the season to be slowest in the treatment moved to deeper water, relative to the other two treatments.

IDENTIFICATION OF CRASSOSTREA SPECIES FROM CHINA USING SNP-BASED MARKERS. Haiyan Wang and Ximing Guo, Haskin Shellfish Research Laboratory, Rutgers University.

China is home to 17 species of oysters and among them, five *Crassostrea* species: *C. hongkongensis*, *C. angulata*, *C. gigas*, *C. sikamea* and *C. ariakensis* are most common and commercially important. These five species often co-exist in the same estuary, and their identification using morphological characteristics is problematic. Genetic markers are needed for rapid and reliable identification of these oysters. Single nucleotide polymorphisms (SNPs) are simple and powerful markers for various genetic analyses. In this study, we developed species-specific SNP markers for the identification of common oysters from China. The mitochondrial cytochrome oxidase I (COI) gene and the nuclear 28S ribosomal RNA gene were used for marker development. DNA sequences from different species were either obtained by direct sequencing or downloaded from GenBank. Sequences were aligned, and species- and genus-specific SNPs were identified. Primers were designed for species/allele-specific amplification to generate fragments of different sizes in each species. A multiplex set of species-specific markers from COI was able to distinguish all five *Crassostrea* species in a single-tube PCR. It also separated *Ostrea* and *Saccostrea* species from *Crassostrea* species with the exception of *C. virginica* and *C. rhizophorae*. The 28S primer set was able to separate *C. hongkongensis*, *C. ariakensis* from other species, as well as *Saccostrea* and *Ostrea* species from *Crassostrea* species (except *C. virginica* and *C. rhizophorae*). The SNP-based markers do not require fluorescence-labeling or post-PCR digestion, providing a simple, fast and reliable method for oyster identification.

DISTRIBUTION OF CRASSOSTREA ARIAKENSIS IN CHINA. Haiyan Wang¹, Lumin Qian², Guofan Zhang³, Xiao Liu⁴, Aimin Wang⁴, Yaohua Shi⁴, Nianzhi Jiao⁵ and Ximing Guo¹. ¹Haskin Shellfish Research Laboratory, Rutgers University, ²Third Institute of Oceanology, Oceanic Administration, PRC, ³Institute of Oceanology, Chinese Academy of Sciences, PRC, ⁴Ocean College, Hainan University, ⁵Center for Marine Environmental Sciences, Xiamen University.

It is commonly assumed that *Crassostrea ariakensis* is synonymous with *C. rivularis* that, according to the literature, is abundant and widely distributed in China. However, at least three species, *C.*

gigas, *C. hongkongensis* and *C. ariakensis*, have been reported as *C. rivularis* in China, creating uncertainties about the distribution of *C. ariakensis*. To determine the distribution of true *C. ariakensis* in China, we collected and classified 2,624 oysters from 50 locations along China's coast using species-specific DNA markers. *C. ariakensis* was found at 10 sites ranging from northern Shandong to Guangxi. While *C. ariakensis* had a wide geographical distribution, its occurrence within its range is patchy or scarce. Overall, *C. ariakensis* accounted for only 9.5% of all oysters collected. Large *C. ariakensis* populations were found in only three areas: Jiulong River in Fujian, Dongzao Harbor near Yangtze River and Yellow River basin in Bohai Sea, with none observed in-between. In Guangxi and Guangdong, *C. ariakensis* was present in all samples collected at low frequencies (0.5–17.5%). All three major populations are found in or near large rivers, and the absence of rivers may be a factor contributing to the fragmented distribution. At all sites, *C. ariakensis* co-existed with other species: *C. gigas* in Bohai Sea; *C. sikamea* at Dongzao Harbor; and *C. hongkongensis*, *C. angulata*, *C. sikamea* and *Saccostrea* species in southern China. *C. ariakensis* tended to occur subtidally, while other species were often found intertidally.

LOSS OF ALLELE DIVERSITY IN AN INTRODUCED POPULATION OF THE HERMAPHRODITIC BAY SCALLOP *ARGOPECTEN IRRADIANS*. Lingling Wang¹, Huan Zhang², Linsheng Song² and Ximing Guo¹. ¹Haskin Shellfish Research Laboratory, Rutgers, US, ²Institute of Oceanology, CAS, China.

The bay scallop, *Argopecten irradians*, a hermaphroditic bivalve native to the Atlantic coast of the United States, was introduced to China for aquaculture production in 1982. Now bay scallops dominate scallop farming in China and account for more than half of all scallop production. Bay scallop aquaculture is exclusively hatchery based and as the initial introduction consisted of only 27 scallops, there have been concerns about inbreeding and inbreeding depression in cultured populations in China. In this study, we used 11 simple sequence repeat (SSR) markers to compare genetic variation in cultured populations from China with that in a natural population from America. Eight of the 11 loci were polymorphic in all populations studied. Although the difference in heterozygosity was small, the Chinese populations lost 10 of the 45 alleles (22%) found in the wild population. The reduced allele diversity suggests that the Chinese populations experienced a severe bottleneck in genetic diversity during the introduction and subsequent hatchery production. Interestingly, the loss of rare alleles did not result in significant changes in heterozygosity. Fixation index of the Chinese populations were actually lower than that of the wild population, suggesting that the culture Chinese populations may represent a mixture of scallops from different introductions or populations. Effects of the reduced allele diversity are not clear at this time, but results of this study highlight the need for

genetic monitoring and selective breeding in order to ensure the genetic health of introduced populations.

DEVELOPMENT AND CHARACTERIZATION OF EST-SSR MARKERS IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*. Yongping Wang and Ximing Guo, Rutgers University.

Simple sequence repeat (SSR) markers were developed from expressed sequence tags (ESTs) in the eastern oyster (*Crassostrea virginica*). ESTs of the eastern oyster were downloaded from GenBank and screened for SSRs that contained at least eight units of di-nucleotide repeats or five units of tri-, tetra-, penta- and hexa-nucleotide repeats. The screening of 9101 ESTs identified 127 (1.4%) SSR-containing sequences. Primers were designed for 88 SSR-containing ESTs with good and sufficient flanking sequences. PCR amplification was successful for 71 (81%) of the primer pairs including 19 pairs amplified fragments that were significantly longer than the expected size, probably due to introns. Sixty-six pairs that produced fragments size shorter than 800 bp were screened for polymorphism in five oysters from three populations using polyacrylamide gels, and 53 of them (80%) were polymorphic. Forty-five SSRs were labeled and genotyped in 30 oysters from three populations using an automated sequencer. Five of the SSRs amplified more than two fragments per oyster, suggesting that they belonged to duplicated loci, but they can still be used for segregation analysis. The remaining 40 SSRs had two alleles per individual including seven with null-alleles. In the 30 oysters analyzed, the SSRs had an average of 9.6 alleles per locus, ranging from 2 to 24. All 45 markers were used for segregation analysis in a family with 34 progeny. None of the 45 loci showed significant deviation from Mendelian ratios. This study demonstrates that ESTs are valuable resources for the development of genetic markers in the eastern oyster.

IDENTIFICATION OF *CRASSOSTREA ARIAKENSIS* USING ITS LENGTH POLYMORPHISM. Yongping Wang and Ximing Guo, Haskin Shellfish Research Laboratory, Institute of Marine.

Oysters cannot be reliably identified using morphological characteristics alone. In an effort to develop genetic markers for oyster identification, we studied length polymorphism in internal transcribed spacers (ITS) between ribosomal RNA genes in 12 common species of Ostreidae: *Crassostrea virginica*, *C. rhizophorae*, *C. gigas*, *C. angulata*, *C. sikamea*, *C. ariakensis*, *C. hongkongensis*, *Saccostrea echinata*, *S. glomerata*, *Ostrea angasi*, *O. edulis*, and *O. conchaphila*. We downloaded and aligned ribosomal RNA sequences from all oyster and some other bivalve species to identify conserved sequences flanking ITS1 and ITS2. We designed two pairs of primers and optimized PCR conditions for simultaneously amplification of ITS1 and ITS2 in a single tube. Amplification was successful in all 12 species, and PCR products were

visualized on high-resolution agarose gels. ITS2 was longer than ITS1 in all *Crassostrea* and *Saccostrea* species, while they were about the same size in three *Ostrea* species. No intraspecific variation in ITS length was detected. Among species, the length of ITS1 and ITS2 was polymorphic and provided unique identification of eight species or species pairs: *C. ariakensis*, *C. hongkongensis*, *C. sikamea*, *O. conchaphila*, *C. virginica*/*C. rhizophorae*, *C. gigas*/*C. angulata*, *S. echinata*/*S. glomerata*, and *O. angasi*/*O. edulis*. Two species within a pair were not distinguishable by ITS length. The ITS assay provides simple, rapid and effective identification of *C. ariakensis* and several other oyster species. Because the primer sequences are conserved, the ITS assay may be useful in the identification of other bivalve species.

NUTRITION RESEARCH IN ECHINODS: CONSIDERATIONS FOR METHODOLOGY. Stephen A. Watts¹, M. L. Powell¹, A. L. Lawrence² and J. M. Lawrence³. ¹University of Alabama at Birmingham, ²Texas A&M University System, ³University of South Florida.

Recent interest in commercial echinoid culture has led to studies of the nutritional requirements for many sea urchin species. As sea urchins are benthic, eurythermal, stenohaline and, in some cases, rheophilic organisms, which feed at relatively slow or irregular rates, consideration of abiotic and biotic factors that affect feeding and growth characteristics can enhance our ability to evaluate nutritional requirements. We are attempting to standardize protocols for nutritional studies in echinoids. Considerations include standardized temperatures (species-specific), salinity, photoperiod, oxygen levels, water quality (including nitrogen levels, pH, hardness and alkalinity, natural vs. artificial seawater), flow rates, and *in situ* bacterial and fungal populations. System design (flow-through or recirculation) must be coupled with appropriate statistical design and evaluation (individual observations vs. group trials). Understanding life-history traits, including behaviors, pathologies, and natural growth variability, is essential. Feeds can include live or preserved natural food and practical, semi-purified and purified feeds. However, evaluation of natural food is of limited value in determining requirements because of lack of information about their content. Formulated (*not* artificial) feeds should be composed of quality ingredients available from commercial sources, whether practical, semi-purified or purified. Formulated feeds must have defined size, shape, texture, stability, and attractability, with defined handling and storage characteristics. Whenever possible, nutrient content should be determined empirically. Feed management strategies must be well defined, including feeding rates and rations. Finally, echinoid nutritional studies should use standardized metrics and responses for cross-species and cross-phylum comparisons.

DEVELOPMENT OF FORMULATED FEEDS IN ECHINODS. Stephen A. Watts¹, A. L. Lawrence², M. L. Powell¹ and J. M. Lawrence³. ¹University of Alabama at Birmingham, ²Texas A&M University System, ³University of South Florida.

Successful sea urchin aquaculture will ultimately depend on high quality, nutritionally-complete, commercially-available feeds. We are developing practical, semi-purified and purified feeds that promote high rates of growth and survival. These feeds require the use of high quality ingredients that can be obtained from reputable commercial vendors. Semi-purified diets can be used to determine dietary requirements and/or toxicities of proximate nutrients in urchins. Purified diets can be used to evaluate requirements for micronutrients, including vitamins and minerals. We are currently evaluating semi-purified, cold-extruded feeds that range from 17 to 41% protein, 15 to 36% carbohydrate, 4 to 12% crude fat (marine and non-marine sources), 1 to 5% crude fiber, and 6 to 50% ash. These nutrients are evaluated using both purified and non-purified sources, both in combination and as the sole source. Amino acid profiles have been calculated to ensure adequate availability of indispensable amino acids. Fatty acid profiles have been determined to evaluate requirements for PUFA or HUFA. Data indicate that specific minerals and vitamins are required for normal physiological function. High production of gonads with marketable color and flavor is now possible. Empirically-derived levels of experimental nutrients are necessary as calculated levels may inaccurately estimate actual levels in the feeds.

GROWTH OF BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, FED VARYING *TETRASELMIS CHUI* CONCENTRATIONS AND ITS EFFECT ON AMMONIA CONCENTRATION. James C. Widman Jr., Shannon Meseck, David J. Veilleux and Mark Dixon. USDOC, NOAA, National Marine Fisheries Service Milford CT.

Bay scallops, *Argopecten irradians irradians*, were grown in semi-static culture systems containing *Tetraselmis chui* at concentrations of 1,000, 3,500, 8,000 and 11,000 cells/ml. Our objective was to determine whether phytoplankton concentrations would affect ammonia levels in the culture system. Microalgal cell concentrations were continuously monitored and maintained by a computer control system. F media was used to grow the *T. chui*. Daily buckets were drained and filled with 15 L of filtered seawater. Twice weekly scallops were removed from the containers and placed in clean 15 L buckets. Every week ammonia levels were measured during a 24 hour period. Scallops grew from initial mean shell heights of 10.5–10.9 mm to final mean shell heights of 15.2–17.9 mm. Scallops grew at similar rates for the first 14 days. After 21, days scallops grown at a cell concentration of 11,000 cells/ml were significantly smaller than those grown at 1000 cells/ml. Throughout the experiment scallops grown at 1,000 and 3,500 cells/ml were not significantly different ($p > 0.05$) from one another. Similarly scallops grown at 3,500 and 8,000 cells/ml grew at

similar rates ($p > 0.05$). Scallops grown at 8,000 and 11,000 cells/ml were always similar ($p > 0.05$) to one another. These results contrast with a previous study that had shown no growth differences when scallops were fed varying concentrations of *T. chui* grown in E media. Ammonia concentrations were never measured above 10 $\mu\text{mol/L}$. There was no relationship between ammonia concentrations observed and scallop growth rates. Scallop survival was greater than 83% in all treatments.

OYSTER AQUACULTURE MAY POSITIVELY AFFECT EELGRASS (*ZOSTERA MARINA* L.) THROUGH ENHANCED SEED PRODUCTION AND GERMINATION.

Lorena M. Wisheart¹, Sally D. Hacker¹, Brett R. Dumbauld² and Jennifer L. Ruesink³. ¹Oregon State University, Zoology Department, Cordley 3029, Corvallis, OR 97331-2914, ²USDA/ARS, ³University of Washington.

The interactions between oyster aquaculture and eelgrass need to be explored to assist shellfish growers in the development of sustainable farms while ensuring ecological integrity in aquaculture areas. Past studies have identified both positive and negative effects of shellfish aquaculture on eelgrass but researchers have yet to address how such activities may affect eelgrass recruitment. We conducted surveys in Willapa Bay, WA and found higher seedling densities in dredged beds than in longlines or eelgrass beds. We hypothesized that this pattern was due to variations in seed density and/or differences in germination. We estimated seed density by counting the number of seeds produced per shoot in each habitat type and found this to be highest in dredged beds and lowest in longlines. We also tested the hypothesis that dredging positively influences germination by adding seeds to each of the three habitat types in areas with eelgrass present and adjacent plots where adult plants were removed. Germination was highest in the eelgrass beds, where, interestingly, eelgrass removal had a positive effect. We found a similar result when seeds were added to control and removal plots at five different eelgrass beds throughout the bay. Higher germination in removal plots suggests that reduced competition for light and other resources may positively influence recruitment. Greater recruitment in dredged beds may thus be due to both enhanced seed densities as well as removal of neighboring adults. Together these studies suggest ground culture practices may positively affect eelgrass recruitment while longlines may have a negative effect.

GENETIC DIFFERENTIATION AMONG FOUR *CRASSOSTREA ARIAKENSIS* POPULATIONS IN ASIA BY MICRO-SATELLITE POLYMORPHISM. Jie Xiao, Jan F. Cordes and Kimberly S. Reece. Virginia Institute of Marine Science, 1208 Greates Road, Gloucester Point, VA 23062.

Crassostrea ariakensis is being considered for introduction into Chesapeake Bay to help revive the declining native oyster industry and bolster the local ecosystem. Little is known, however, about

wild populations of *C. ariakensis* in its native region, including native distributions, overall genetic diversity, genetic structure, and levels of gene flow. Several discontinuous natural populations have been identified along a wide geographic range in the western Pacific. It is still unclear whether these all are natural populations or whether some are a result of anthropogenic transportations. We studied the genetic variance among four wild populations of *C. ariakensis* from Ariake Bay, Japan, Kahwa River, South Korea, the Yellow River basin in northern China, and Beihai in southern China, using novel microsatellite makers. Initial results are reported for 3 loci (CarG110, CarI19-6a, CarI1-70) developed from *C. ariakensis* partial genomic libraries and screened for the presence of null alleles in eight family crosses. Estimated multi-locus *F_{st}* (0.0168) values were highly significant for all samples, indicating heterogeneous populations exist in these regions. Single locus *F_{st}* and *P* values are quite variable among these loci, and additional markers are being developed to further test the null hypothesis of population homogeneity. These preliminary results indicate genetic structure exists among populations of *C. ariakensis* in its native region and suggest that microsatellite markers could serve as efficient genetic tags for monitoring *C. ariakensis* introduced into the Chesapeake Bay from different native gene pools.

GENETIC VARIATION IN SURVIVAL AND POST-STARVATION GROWTH RECOVERY OF BIVALVE LARVAE (*CRASSOSTREA GIGAS*). Pauline C. Yu and Donal T. Manahan, University of Southern California, Department of Biological Sciences, Division of Marine Environmental Biology, Los Angeles, CA 90089-0371.

Defining the "point of no return" is of importance for larvae growing in nutrient-poor environments. We tested different larval families of *C. gigas* for their starvation tolerance and ability to recover once fed, following prolonged starvation. Larvae were capable of surviving for over six weeks without food, representing a >6-fold increase over theoretical limitations based on utilization of energy reserves in eggs. Such larvae grew upon feeding at rates comparable to sibling larvae fed at day two. Under our experimental conditions, the "point of no return" for some fraction of a larval cohort far exceeded theoretical expectations. Larvae did not down-regulate metabolism, as respiration rates were maintained at $\sim 12 \text{ pmol larva}^{-1} \text{ hr}^{-1}$ throughout the period tested for food deprivation. Also, protein content of larvae was conserved in the absence of food with up to 47% of day-2 content being present even after 24 days. Genotypic differences in larval survival and recovery were observed. Eggs from single females showed 2-fold differences in starvation resistance when fertilized with different males, implying important genetic-physiological interactions regarding use of egg energy reserves. When comparing sibling larvae from multiple genetic crosses, size at day 6 for larvae fed from day 2 ("growth heterosis") correlated positively ($P = 0.02$) with time to 50% survivorship for larvae of the same family that were unfed

from day two. We propose that common mechanisms of physiological efficiency might be the bases for growth heterosis under high-food conditions and increased larval survival in the absence of food.

EFFECTS OF FLUID SHEAR ON RED ABALONE SPERM-EGG INTERACTIONS. Richard Zimmer and Jeffrey A. Riffell, UCLA.

Fertilization rate is an important factor mediating the production of offspring and, hence, population dynamics. For marine organisms that broadcast their sperm and eggs into the sea, surprisingly little is known about the mechanisms controlling sperm-egg interactions. Here, we investigated hydrodynamic effects on fertilization in red abalone (*Haliotis rufescens*). Experiments were

performed in laminar-shear flows that simulated important aspects of small-scale turbulence within natural habitats. Fertilization rates were determined over a wide range of gamete concentration and shears created in a Taylor-Couette flow tank and using a new application of infrared laser and computer-assisted video imaging technologies. For red abalone, shears of $< 0.1/s$ maximized sperm chemotaxis, gamete encounter rates, and fertilization success. Fertilization was subsequently well explained by numerical models that took into account cell shapes, sizes, and propulsive forces generated by sperm swimming, as well as shear forces imposed by the flow. These models, thus, established the relative contributions of active sperm behavior and passive physical transport to sexual reproductive processes. Combined findings have value in forecasting field sites that maximize offspring production, for transplants, or outplants, of adult brood stock.

ABSTRACT Over five million spat of the king scallop, *Pecten maximus* (L.) were collected accidentally in the North Water of Mulroy Bay in County Donegal, Ireland in the summer of 1979. This large natural settlement, by far the greatest number obtained at the time in any European trial, led to research investigations in 1980 and 1981 to support the development of this site as a scallop spat collection center. A combination of gonad monitoring, plankton sampling, spat settlement and spat collection trials were used to develop a technique for predicting the date of the scallop spatfall to maximize the yield of scallop spat. A technique for forecasting the date of peak spatfall involving installation of spat collectors when the mean shell length of scallop larvae was 180 μ m and 50% of the larval cohort exceeded this size was developed. Unlike other sites studied, peak spat collection occurred at 4 m beneath the water surface. Since its development, this technique for prediction of the date of the peak collection has been used commercially, and for illustrative purposes data from 2002 have been provided. The development and application of this forecasting technique has assisted in the collection of millions of scallop spat for ongrowing trials by the scallop culture industry.

KEY WORDS: *Pecten maximus*, prediction, scallop settlement, spat collection, spatfall

INTRODUCTION

Many commercial scallop fisheries currently exploited in European waters are protected against overfishing by legislation applied to fishing gear; in terms of the number, type and specification of dredges; to landings in terms of the quantity and minimum shell length of the catch and to the duration of the fishing season. All of these precautionary measures are designed to prevent existing resources becoming further diminished or potentially exhausted beyond repair and to allow time for the natural recovery of the resource.

Faced with similar restrictive practices, fishermen in Japan adopted a more proactive role towards conservation and implemented measures to expand resources by the transplantation or reseedling of aquatic animals. The development of methods for the mass production of juveniles of selected species in waters suitable for breeding and the subsequent release of these juveniles to the oceans has resulted in dramatically increased yields from several fisheries. Noteworthy in this context is the successful expansion of Japanese scallop cultivation, annual landings increasing from approximately 9,000 t during the 1960s to consistently over 500,000 t since 1995. The success of this approach to scallop fishery management and resource expansion encouraged many European countries to implement scallop research programs during the 1980s with a view to emulating this success.

Early spat collection trials in France, Spain, Scotland, Isle of Man and England showed considerable annual fluctuations in the number of spat per collector and generally disappointing yields compared with results in Japan (Buestel et al. 1976, Pickett 1977, Ventilla 1977a, 1977b, Mason & Drinkwater 1978, Brand et al. 1980, Roman et al. 1985). Scottish trials in which spat collectors were installed at regular intervals over a 4–6 wk period demonstrated the existence of an optimum date for peak spat collection. Temporal variations in the date of the peak spat collection over

five years ranged from late June to early August (Ventilla 1977a, 1977b, Slater, 1978, 1979, 1980). In some years this peak could rise and fall within a one-week period and in other years be extended over a two- to three-week period (Ventilla 1977a, 1977b). Installing spat collectors in the sea either before or after the date of peak spatfall could dramatically reduce the yield of spat by up to 75%. Clearly for natural spat collection to be successful in the provision of an abundant and reliable source of seed for aquaculture and fishery enhancement, there was a need for a spatfall prediction technique similar to that used in Japan.

Despite significant research effort on king scallops since the early 80's commercial scallop cultivation in Europe has not developed and in countries where fishery landings have been expanded, such increases have resulted only from further exploitation of already overfished natural resources. The major limitation to the scale of any scallop farming or stock enhancement program remains as the availability of a consistently large and reliable source of juvenile scallops or spat. Worldwide in those countries where commercial scallop cultivation has developed, for example Japan, China and Chile, problems associated with the provision of a regular supply of scallop spat have first been overcome.

In 1979, a local aquaculture co-operative, the North Water Co-operative Soc. Ltd., during attempts to capture mussel spat, *Mytilus edulis* (L.), accidentally collected on 12-mm diameter polypropylene rope over 5 million scallop spat in the North Water of Mulroy Bay in County Donegal, by far the greatest number obtained at the time in any European trial (Minchin 1980). As a result of this exceptionally large settlement, research trials commenced to support the exploitation of the site as a scallop spat collection center.

Research during 1980 and 1981 focused on gonad monitoring, plankton analysis, spat settlement and spat collection trials to develop a technique for prediction of the date and location of the peak scallop spatfall. This study provides results from these investigations that led to the development of techniques for prediction of the date of peak spatfall and provides for illustrative purposes results obtained during commercial application of this predictive technique in 2002.

MATERIALS AND METHODS

The Location

Mulroy Bay is located in County Donegal in the northwest of Ireland (Fig. 1). It is a sheltered, marine lough connected to the open sea by a series of long and narrow channels. The Bay is well sheltered from excessive exposure and no oceanic swells are able to penetrate into the two main parts, the Broad Water and the North Water. Seawater enters the Bay through the Narrows and flows into the Broad Water before passing through the Moross Channel into a further and even more enclosed sea lough, the North Water, which is approximately 3 km by 1 km in size. Water depths extend to 51 m in the North Water and the bathymetry of the lough is available on Admiralty Chart No. 2698. Resulting from this topography, the tidal range within the Bay and water exchange with the open sea is much diminished. The Bay provides an ideal location for shellfish spat production, because larvae produced by natural populations in the Bay are retained and settle within the system rather than being dispersed as occurs in more open waters.

The sea lough is surrounded by poor quality land with a low population density supporting an agricultural community dominated by small farms. At the head of the lough is the village of Milford (population 1,334) that forms the gateway to both the Fanad Peninsula down the eastern side of Mulroy Bay and the Rosguill Peninsula down the western side of Mulroy Bay. The only significant employers in the area are Marine Harvest (Fanad), a salmon farming company with approximately 150 staff.

Gonad Monitoring

Samples of adult king scallops for gonad assessment were dredged from around the Stookans, Massmount Bay, North Water of Mulroy Bay using a lightweight converted oyster dredge (Fig. 1). In 1980 samples comprising 22–27 individuals of mean shell height 113.4 ± 1.8 mm were collected at intervals ranging from 4–13 days (mean = 8.4 days) between June 5 and August 30, 1980. In 1981 samples comprising 23–25 individuals of mean shell height 113.8 ± 1.2 mm were collected at intervals ranging from 5–10 days (mean = 6.8 days) between June 10 and July 8, 1981. Soft tissues were dissected from each scallop, pooled and weighed. Gonad index was determined according to the following formula:

$$\text{Gonad Index (\%)} = \frac{\text{Total wt. of gonad (g)}}{\text{Total wt. of soft tissue (g)}} \times \frac{100}{1}$$

To account for minor variations in the size of scallops from week to week, the relative gonad height (RGH) was calculated using the equation:

$$\text{RGH (g.mm}^{-3}\text{)} = \frac{\text{Mean wt. of gonad in g}}{(\text{Mean shell ht. in mm})^3} \times 10^6$$

Following the introduction into Irish legislation of the Mulroy Bay (North Water and Moross Channel) (Prohibition on Dredging for Escallops) Bye Law No. 625, 1982 to protect broodstock scallops in this site from exploitation and hence conserve the area as a national center for scallop spat collection, farmed scallops from a single year-class and of a size greater than 90 mm shell height were held at 5-m depth on longlines at Deegagh Point in the Broad Water of Mulroy Bay (Fig. 1) and used as a source of adult stock for gonad monitoring.

Larval Sampling

In 1980 plankton samples for monitoring the occurrence and development of scallop larvae were obtained from a site at Lurgacloghan on the western side of the North Water (Fig. 1) within the site licensed to Deegagh Point Shellfish Ltd. for scallop aquaculture. Samples comprising a single vertical haul were collected using a 63- μ m mesh plankton net with a 30-cm diameter opening, hauled at a rate of 5 m.min⁻¹, from 20 m to the water surface. All planktonic larvae were added to a 1-L, wide-mouthed, plastic jar containing 100 mL of formaldehyde to immediately preserve the living material. In the laboratory, samples were placed in a 1-L beaker and gently stirred. Bivalve larvae, being slightly heavier than most other planktonic organisms, rapidly accumulated in the center of the beaker as a result of the gentle centrifugal force and were transferred to 25 mL Sterilin® storage containers using a 10 mL pipette. Larvae were examined on a Sedgewick Rafter counting cell using $\times 40$ and $\times 100$ magnification on an Olympus KH series microscope. Scallop larvae were identified from their morphological features and measured using an eyepiece graticule at $\times 100$ magnification (Slater 2005b). Identification was possible as a result of expertise gained during hatchery rearing studies with *P. maximus* (L.).

The distribution of scallop larvae in the North Water was investigated by measuring larval abundance at eight sites in the North Water of Mulroy Bay. Samples comprising a single vertical plankton haul from 15 m to the water surface were collected on July 16, 1980 between 10.00 PM to 12.00 PM and repeated on July

Figure 1. Mulroy Bay on the northwest coast of Ireland.

18, 1980 between 9.00 PM AND 11.00 PM. Weather and sea conditions on both these occasions were ideal for quantitative work of this type.

In 1981 plankton samples for monitoring the occurrence and development of scallop larvae were obtained from the same site at Lurgacloghan on the western side of the North Water using similar techniques to those outlined earlier. A single vertical haul from 20 m to the water surface provided sufficient numbers of scallop larvae for analysis. From 1985 onwards, following use of TBT (tributyl-tin) antifoulants by salmon farms in the Bay, three vertical hauls were collected at this site to provide sufficient scallop larvae for analysis (Minchin et al. 1987).

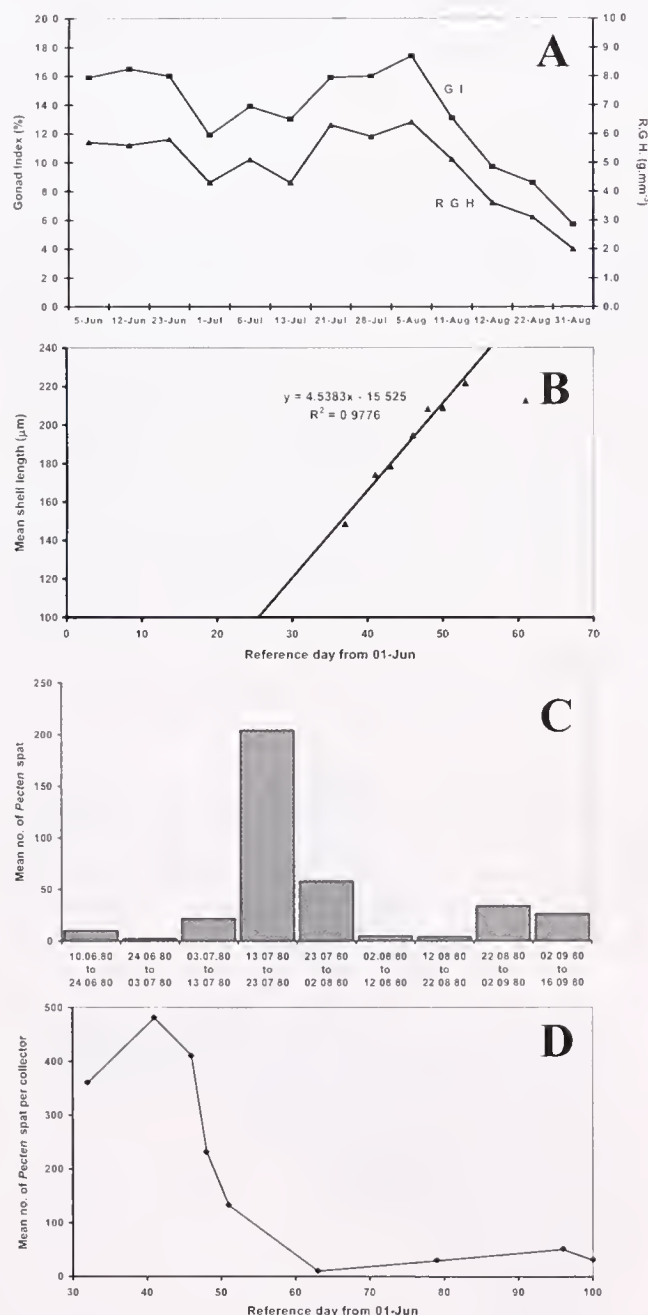

Figure 2. Gonad monitoring (A), larval growth rate (B), spat settlement (C) and scallop spat collection at the site north of Croagh Island (D) during 1980.

Indicator Collectors

Indicator collectors were used to provide data on time and intensity of settlement of scallop spat. These consisted of a piece of 6-mm Netlon® mesh of 0.8 m × 0.3 m dimensions, rolled twice along the long axis into a cylindrical shape and fixed using cable ties.

In 1980 indicator collectors were attached to ropes at 4 m, 8 m and 12 m above the seabed and installed in a 15-m deep site at the north of Croagh Island (Fig. 1). After 10–11 days immersion, these indicator collectors were exchanged for a new set of collectors for spat settlement. Bivalve spat settling during the 10- to 11-day period were removed from the collectors by immersion in 20% sodium hypochlorite in fresh water for 3 min. The solution was sieved through a 90-μm mesh sieve to collect the recently settled bivalve spat (Davies 1974). Examination of bivalve spat was performed on a Sedgewick Rafter counting cell at ×40 and ×100 magnification. Scallop spat were identified and counted from each indicator collector.

In 1981 trials with indicator collectors were repeated in a 23-m deep site in Bally Hork Bay, the site exhibiting higher spat collection results than the north of Croagh Island site in 1980 (Fig. 1). Collectors were attached at 5 m, 10 m and 15 m beneath the water surface, irrespective of the tidal state, based on the 1980 data on variation in settlement intensity with depth. Because the 1980 results showed a small settlement in early June, the indicator collector trial in 1981 was extended to cover the period May 27 to September 4.

Spat Collection

Spat collectors used in 1980 consisted of polyethylene woven-filament mesh bags of 0.45 m × 0.45 m dimensions and mesh size 6 mm × 3 mm. Each mesh bag contained 2 m of monofilament nylon salmon netting provided by the North Western Regional Fisheries Board, following confiscation from illegal fishing activi-

Figure 3. The number of scallop larvae, *P. maximus* in one vertical plankton haul on July 16 and July 18 1980.

TABLE 1.

Total number from each date	1805	2410	2055	1160	665	56	153	261	158	
Mean number per collector	361	482	411	232	133	11	31	52	32	

ties. Collector bags were attached to individually anchored 12-mm diameter polypropylene ropes at 2-m intervals from 2–10 m above the seabed to provide information concerning the optimal depth for collection in the 15-m deep site north of Croaghan Island. A 20-cm diameter subsurface float was attached to each rope at 11 m above the seabed to reduce the action of wind and waves on collector bags. A 30-cm diameter marker buoy was attached to the top of the rope to mark the position of the collector line. A total of nine such ropes were positioned in the site from July 2 to September 2, 1980.

Following the larval distribution study, two ropes, each with five collector bags attached as previously mentioned, were positioned on July 17, 1980 in Bally Hork Bay, the site with the highest larval numbers. Because of limited supplies of the polyethylene woven-filament collectors, collector bags at this site comprised 1 m × 0.5 m Netlon® oyster bags of 6 mm × 6 mm mesh size containing 6 m of monofilament mesh salmon netting with the ends of the bags closed at right angles to each other. The spat collection efficiency of this type of collector, which had been successfully used in previous Scottish trials, was compared with the polyethylene woven filament collector in the north of Croaghan island site. Sorting of all collector bags commenced from late October onwards and continued over a two-week period. Collector bags and inner net filler were individually washed into tanks of seawater and live scallop spat from each bag counted individually.

Following the 1980 trials, which demonstrated increased numbers of *Pecten* spat with increased distance from the seabed at two sites in the North Water, collector bags used during 1981 were positioned at 2-m intervals from 2 m to 10 m beneath the water surface. All collector bags used were of the polyethylene woven-filament type and were positioned in Bally Hork Bay, the more productive of the two sites in the North Water and four sites in the Broad Water investigated during 1980.

Spat collection data from 2002 were provided by the pioneering scallop farming company, Deegagh Point Shellfish Ltd., established in 1980 to commercially exploit king scallop spat collection in Mulroy Bay. Collector bags used for commercial spat collection were 0.8 m × 0.3 m dimensions and 5 mm × 3 mm mesh size and filled with 2 m × 1 m of lightweight garden netting (Netlon®) of 6 mm × 6 mm mesh size. All collector bags were suspended from 300 m longlines, submerged 4 m beneath the water surface and attached to the shore at one end in a site at Lurgacloghan (Fig. 1). Spat collectors were installed over a 3-day period at the date of peak spatfall determined using gonad analysis and scallop larval monitoring.

RESULTS

1980 Gonad Monitoring

A large partial spawning was recorded from June 23 to July 1, GI decreasing from 16.0% to 11.9%. Following a rematuration phase over one week, a second smaller partial spawning was recorded from July 6 to 13, with GI decreasing from 13.9% to 13.0%. This smaller second partial spawning was more clearly evident in the RGH results, which accounted for shell size, there being a 3-mm increase in shell length of scallops used for the assessment on July 13, compared with July 6. Following gonad filling during the remainder of July, a larger and more complete spawning commenced in early August and continued throughout that month (Fig. 2A).

The trend in results for gonad index (GI), which relates the gonad weight to the total soft tissue weight, was very similar to that for relative gonad height (RGH), which relates the gonad weight to the size of the adult shell (Fig. 2A). There was a highly significant correlation between GI and RGH ($F_{1,11} = 300.158$, $P < 0.001$).

1980 Larval Monitoring

Larvae of the scallop, *Pecten maximus*, were first recorded on July 7 at a mean shell length of 148.5 µm and were present in all samples until July 31. The number of scallop larvae measured in each sample ranged from 3–100 during this period. Larval growth rate was approximately 4.54 µm.day⁻¹ (Fig. 2B). Extrapolation of

Figure 4. Variation in king scallop spat collection with depth above the seabed at the site north of Croaghan Island during 1980.

the larval growth trendline to a shell length of 100 μm , a size usually achieved in the hatchery at three days old, suggested that these larvae originated from a spawning on June 22, corresponding with the first partial spawning recorded by gonad monitoring between June 23 and July 1. The final result on July 31 of 212.7 μm , based on only three larvae, showed a decline from the previous result on July 23 of 221.7 μm . This decline was attributed to the settlement of larger larvae from the plankton at the same time as the few remaining planktonic larvae continued to grow.

Quantitative assessment of the distribution of scallop larvae on July 16 and July 18 showed greater abundance of scallop larvae in Bally Hork Bay (Fig. 3).

Scallop larvae on the two sampling dates had an average shell

length of 194.5 μm and 208.5 μm respectively (i.e., near settlement size).

1980 Indicator Collectors

Low numbers of scallop spat settled on the first set of indicator collectors immersed on June 10 and lifted on June 24 in the site north of Croaghan Island, showing that some spawning activity had occurred prior to June 10. Peak settlement intensity occurred between July 13–23 with an average of 204 spat per collector (Fig. 2C). Settlement intensity varied with distance above the seabed in this 15-m deep site with the indicator collectors situated 8 m above the seabed (i.e., in midwater exhibiting the highest settlement intensity).

1980 Spat Collectors

Results of the spat collection trial at the site north of Croaghan Island, a site exhibiting only 7 and 3 scallop larvae on July 16 and July 18 respectively are provided in Table 1. Peak scallop spat collection occurred from July 11–16 with an average of 450 *Pecten* spat per collector (Fig. 2D). Given a 20-day larval life for this species, a typical value from hatchery production of this species, peak spat collection corresponded to the large partial spawning recorded from June 23 to July 1. A much smaller peak in spat collection on September 4 yielding approximately 50 *Pecten* spat per collector corresponded to the more complete August spawning. Spat collectors installed in Bally Hork Bay, the site with the highest larval counts on July 16 and July 18, yielded an average of 2,100 *Pecten* spat per collector, although these results are not comparable because different collectors were used in the two sites. In both sites increased numbers of *Pecten* spat were obtained with increased distance of the collector bag above the seabed (Fig. 4).

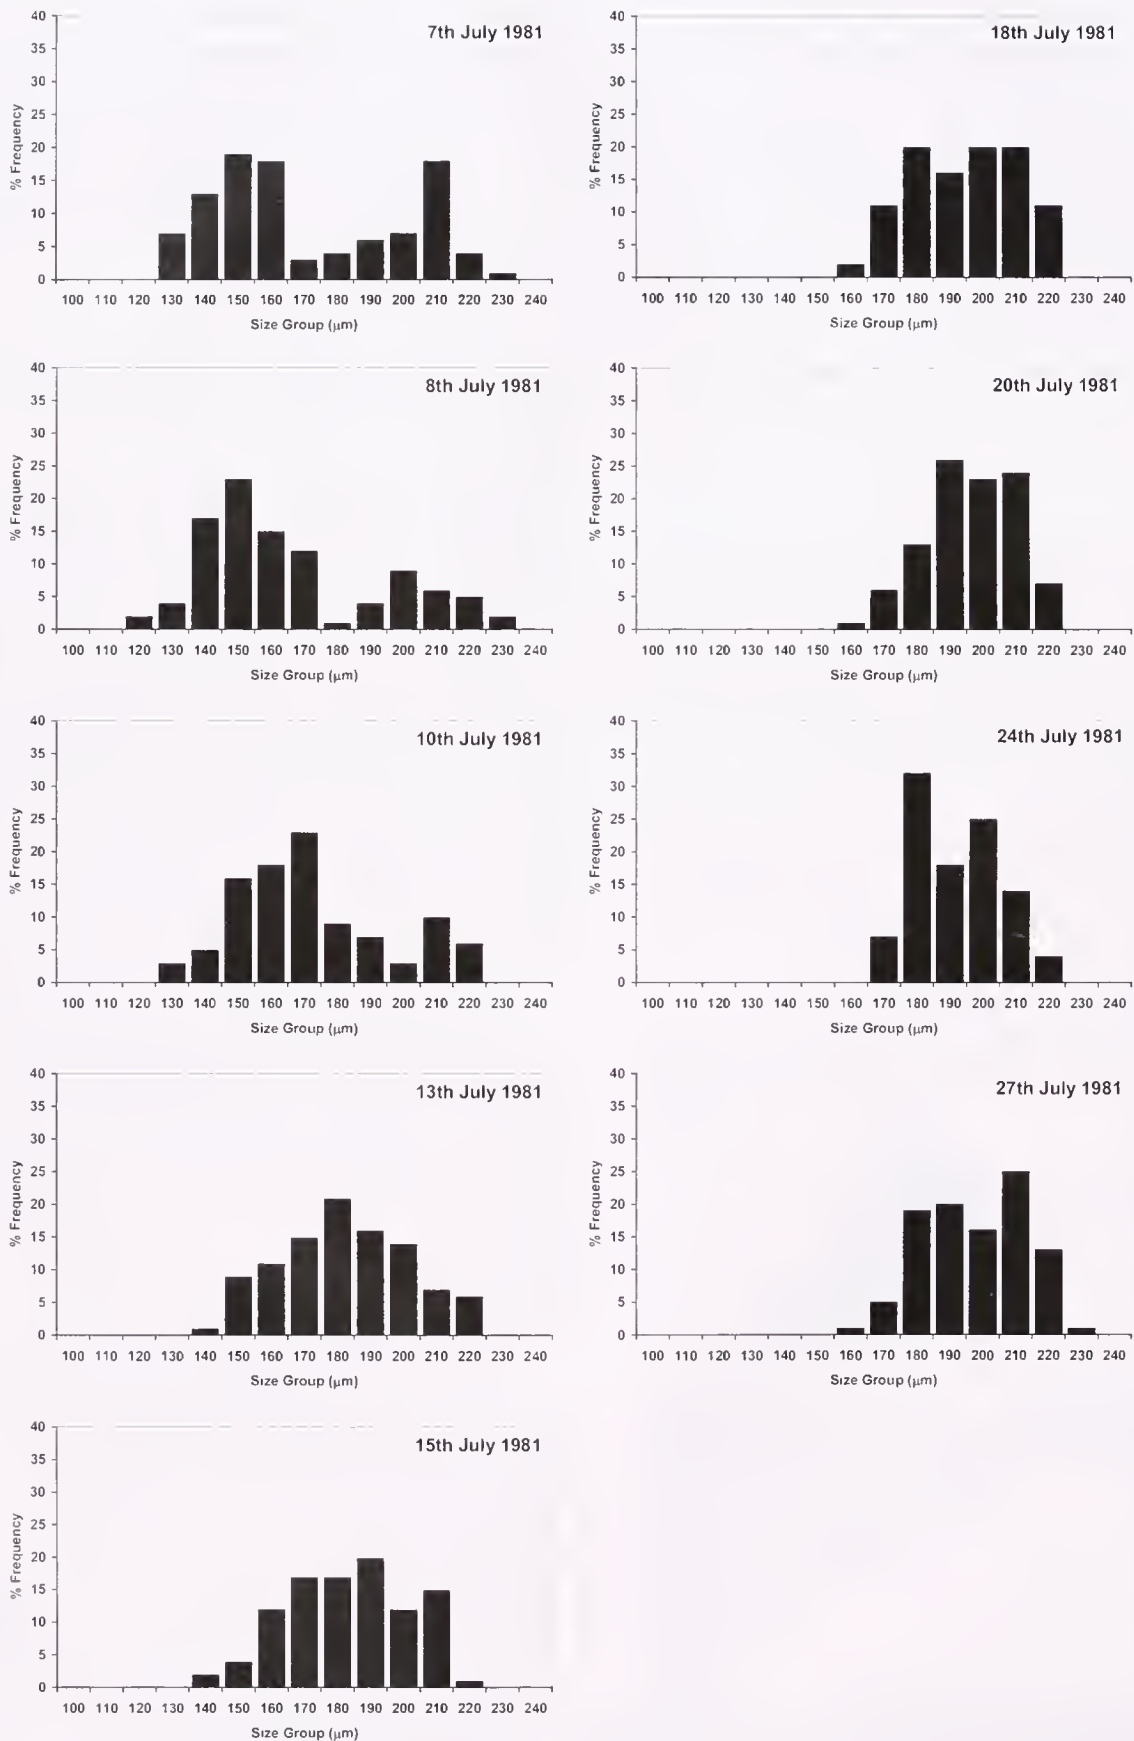

Figure 6. Size distribution analysis of *P. maximus* larval shell length from July 7 to July 27, 1981.

Figure 7. Variation in the percentage of *P. maximus* scallop larvae $\geq 170 \mu\text{m}$, $180 \mu\text{m}$, $190 \mu\text{m}$, $200 \mu\text{m}$, $210 \mu\text{m}$ and $220 \mu\text{m}$ in Bally Hork Bay during 1981.

1981 Gonad Monitoring

A small partial spawning occurred between June 10–20, with GI decreasing from 14.3% to 13.3%, followed by a short rematuration phase and a second larger partial spawning from 26 June to July 2 with GI decreasing from 14.0% to 11.4% (Fig. 5A). Similar to 1980 there was a highly significant correlation between GI and RGH in 1981 ($F_{1,5} = 1083.71$, $P < 0.001$).

1981 Larval Monitoring

Larvae of the scallop, *P. maximus*, were first recorded on June 20 at a mean shell length of $146 \mu\text{m}$ (Table 2). On the July 7 size distribution analysis of larvae showed the presence of two larval batches (Fig. 6). The larval batch comprising larger-sized larvae was not recorded after July 13. Between July 13 to July 30 size distribution analysis showed the presence of only one larval batch.

Scallop larval growth rates were approximately $4.36 \mu\text{m}\cdot\text{day}^{-1}$ for the first larval batch and $5.68 \mu\text{m}\cdot\text{day}^{-1}$ for the second larval batch (Fig. 5B). Extrapolation of the larval growth trendlines to a shell length of $100 \mu\text{m}$, a size usually achieved in the hatchery at three days old, suggested that the first larval batch originated from a spawning on June 6, a time prior to the commencement of scallop gonad monitoring and the second larval batch originated from a spawning on June 25 corresponding with the spawning recorded using GI between June 26 to July 2. Above $200 \mu\text{m}$ both larval batches exhibited deviations from the straight line best-fit attributed to the settlement of larger larvae from the plankton at the same time as remaining planktonic larvae continued to grow.

Larval shell length data from the more abundant second batch of larvae (Table 2) were analyzed in terms of the percentage of larvae greater than or equal to $170 \mu\text{m}$, $180 \mu\text{m}$, $190 \mu\text{m}$, $200 \mu\text{m}$, $210 \mu\text{m}$ and $220 \mu\text{m}$ on each sampling occasion between July 7 and 27 (Fig. 7). The objective of this analysis was the development of a predictive model similar to that used in Japan in which a critical size and a percentage greater than or equal to that size are used to identify the date of the peak spat collection.

1981 Indicator Collectors

Data from indicator collectors in Bally Hork Bay demonstrated that scallop spat settlement during May and June was negligible. Heavy settlement intensity occurred on the two sets of indicator collectors used during the period June 30 to July 20, with a mean settlement intensity of 688 and 849 spat per indicator collector respectively (Fig. 5C). Settlement intensity varied with distance from the water surface in this 23-m deep site with the indicator collectors situated 10 m below the water surface exhibiting the highest settlement intensity.

1981 Spat Collectors

Spat collection in Bally Hork Bay peaked from July 8–14, slightly earlier than in 1980 (Table 3, Fig. 5D). Collector bags immersed during this period yielded over 3,000 spat per collector. Spatfall corresponded with the spawning period identified by GI from June 26 to July 2 and the spawning date on June 25 estimated by extrapolation of the larval trendline from the second larval batch monitored over the period July 7–30. Peak scallop spat collection at the Bally Hork Bay site in 1981 occurred 4 m beneath the water surface (Fig. 8).

Summary of the 1980 and 1981 Experimental Programs

The 1980 experimental program demonstrated that a spawning from June 23 to July 1 resulted in larvae that were first identified on July 7 at a mean shell length of approximately $150 \mu\text{m}$. Larval growth rate was $4.54 \mu\text{m}\cdot\text{day}^{-1}$. Spat collection intensity peaked from July 11–16, a time at which the mean shell length of larvae was between $174 \mu\text{m}$ to $194.5 \mu\text{m}$. Increased spat collection intensity occurred in Bally Hork Bay, a site in which the highest larval concentration was recorded, compared with the north of Croagh Island site. In both sites increased spat collection occurred with increased distance from the seabed.

The 1981 experimental program reported two spawnings from June 10 to 20 and June 26 to July 2 resulting in larvae from each

that were first identified on June 20 and July 7 respectively at a mean shell length of approximately 150 μm . Larval growth rate for the two larval batches were 4.36 $\mu\text{m}\cdot\text{day}^{-1}$ and 5.68 $\mu\text{m}\cdot\text{day}^{-1}$. Spat collection intensity in Bally Hork Bay peaked from July 8 to 14, a time at which the mean shell length of larvae was between 156 μm to 194.5 μm . Scallop spat collection peaked 4 m beneath the water surface.

Both experimental programs demonstrated that peak spat collection could be predicted using a combination of gonad monitoring and larval development. Gonad monitoring demonstrated that a spawning had occurred, though this did not necessarily infer that significant numbers of larvae has been produced or that spat collection would occur. Larval development was more useful as a means of spatfall prediction, because it focused on the developmental stage immediately prior to settlement. Based on the data from the two years of experimental investigation a hypothesis was proposed that the date of peak spat collection occurred when the mean shell length of larvae was 180 μm (Fig. 5B) and 50% of the larval cohort exceeded 180 μm (Fig. 7). Using these two models the dates for peak spat collection in 1981 would have been predicted as the July 11–12 by the mean shell length model and July 11–12 by the percentage greater than 180- μm model. The installation of collector bags on these dates would have resulted in excellent yields of scallop spat in 1981.

Commercial application of the technique in 2002

Since its development in the early 80s these techniques for prediction of the date of the scallop spatfall have been used commercially in the North Water of Mulroy Bay. Data from the 2002 commercial collection of spat have been provided for illustrative purposes. Monitoring of GI and RGH of scallops indicated that a partial spawning occurred from July 4 to July 11, 2002 with GI decreasing from 15.6% to 14.0% (Fig. 9A).

Low numbers of larvae of the scallop, *Pecten maximus*, were recorded on June 24, the first day of sampling at a mean shell length of 133.6 μm (Table 4). The growth rate of these larvae was approximately 4.19 $\mu\text{m}\cdot\text{day}^{-1}$ (Fig. 9B). Extrapolation of the larval growth trendline suggested that this larval batch originated from a spawning on June 13, a time prior to the commencement of gonad monitoring. Size distribution analysis of larvae collected on July 9 showed the presence of an abundant larval batch of shell length 120 μm to 140 μm and the presence of at least one less abundant cohort corresponding to an earlier spawning(s). Micro-

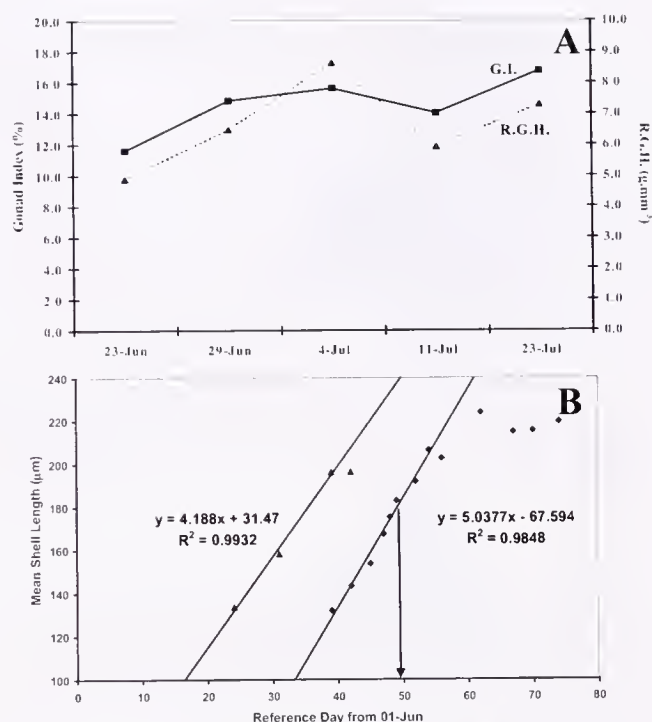

Figure 9. Gonad monitoring (A) and larval growth rate at Lurgacloghan in the North Water of Mulroy Bay (B) during 2002.

analysis of the size distribution data of samples from July 15 to July 22 could be used to suggest that these scallop larvae represented one, two, three or even four larval cohorts with overlapping size distributions. However, because each larval size distribution in this period represented from 28–100 larval measurements, a number considered too low for microanalysis of data, this was not performed in this study (Fig. 10). Instead larvae from July 9 and July 12, samples have been considered as comprising two larval batches and larvae from July 15 onwards as one larval

Figure 11. The percentage of *P. maximus* larvae >180 µm from the second larval batch during 2002.

batch. The growth rate of larvae in the second, more abundant, larval batch was approximately $5.04 \mu\text{m}\cdot\text{day}^{-1}$ (Fig. 9B). Extrapolation of the larval growth trendline suggested that the second larval batch originated from a spawning on June 30, somewhat earlier than the July 4–11 spawning period identified using GI monitoring. Growth rate of the second larval batch, as in 1980 and 1981, decreased above 200 µm and was attributed to the settlement of larger larvae at the same time as the remaining planktonic larvae continued to grow. Using the prediction model developed in 1981, date of peak spat collection in 2002 was forecast as July 19, using both the mean shell length model (Fig. 9B) and the 50% greater than 180 µm model (Fig. 11).

Commercial scallop spat collection yields in excess of 3,000 per collector bag were obtained from collector bags installed on July 19, 2002 and sorted in October 2002.

DISCUSSION

Determination of the spawning time of the scallop, *P. maximus* and thus the time at which larvae should be present in the water can be elucidated using either GI or RGH calculated from pooled tissue weights and mean shell size. The benefit of using more than one measure of reproductive condition was evident from the results of the second spawning in 1980; the small difference in GI results being more clearly evident in the RGH results, which accounted for the increased shell length between the samples. Although individual tissue weights and shell sizes would have provided a measure of the dispersion in reproductive condition within the sample, analytical equipment required for individual measurement was not available in 1980 and 1981. Frequent gonad monitoring at regular weekly intervals was used to ensure the provision of meaningful data. Partial spawnings during the summer, which can be all important in terms of scallop spat production, may be of short duration and be followed by rapid rematuration to pre-spawning levels (Slater 2005a). Sampling intervals greater than weekly could fail to record such partial spawnings. Even with a weekly sampling interval, gonad monitoring alone is not suitable as a tool for spatfall prediction. For example, in 1980 three spawnings were recorded over the duration of the sampling program, however significant numbers of scallop larvae were only recorded from the larger of the two partial spawnings occurring between late June to early July. These results demonstrate one inherent weakness of using gonad monitoring alone, namely that based on gonad results

it would be reasonable to assume that three spawnings should have resulted in three larval batches and hence three spatfalls, with the larger more complete spawning in late August possibly providing the largest spat collection.

Scallop larval growth rates under natural conditions of $4.54 \mu\text{m}\cdot\text{day}^{-1}$ in 1980, $4.36 \mu\text{m}\cdot\text{day}^{-1}$ and $5.68 \mu\text{m}\cdot\text{day}^{-1}$ for the two batches in 1981, and $4.19 \mu\text{m}\cdot\text{day}^{-1}$ and $5.04 \mu\text{m}\cdot\text{day}^{-1}$ in 2002 were comparable with figures reported from hatcheries (Comely 1972, Gruffydd & Beaumont 1972, Le Pennec 1974, 1978). Back extrapolation of the larval growth rate trendline can be used to estimate the spawning date. Comparison of spawning dates provided by gonad monitoring with those provided by back extrapolation of the larval growth rate revealed a second weakness of the former, namely that GI/RGH identified a "spawning period" within which spawning was assumed to have occurred, whereas back extrapolation of the larval growth rate provided a "spawning date." The occurrence of a "spawning date" prior to the commencement of the "spawning period" (Table 5) may occur as an artifact of the sampling frequency used in gonad monitoring, spawning having already commenced before the high GI result at the commencement of the "spawning period" but not having been recorded because of the sampling frequency.

In summary, gonad monitoring can at best be used to provide an indication of the time period when larvae may be present, whereas larval monitoring can be used to provide confirmation that spawning has occurred and that scallop larvae have been produced and are developing normally.

To obtain an indication of the spatial distribution of scallop larvae, numbers of scallop larvae in a single vertical haul from 15 m to the water surface at eight sites in the North Water were determined. Other studies have reported that for quantitative work, plankton samples collected with a pump rather than plankton net provide a better estimate of abundance, however such equipment was not available for this study. Although significant variation in larval numbers between hauls have been reported in the literature, a single haul in the late evening was used in this investigation to allow rapid examination of all samples and the installation of collectors the following day in the site showing highest larval abundance. Quantitative analysis of the numbers of scallop larvae in a single vertical haul in eight sites demonstrated similar distribution patterns in the North Water on two dates in July 1980 (Fig. 3). The higher spat collection intensity in Bally Hork Bay com-

TABLE 5.

Summary of scallop spawning "dates" using larval growth extrapolation and spawning "periods" using gonad index in 1980, 1981 and 2002.

	Spawning "Date" from Larval Growth Extrapolation	Spawning "Period" from Gonad Index
1980 larvae	June 22	June 23–July 1
1981 larvae (batch 1)	June 6	Before sampling commenced
1981 larvae (batch 2)	June 25	June 26–July 2
2002 larvae (batch 1)	June 13	Before sampling commenced
2002 larvae (batch 2)	June 30	July 4–July 11

pared with north of Croaghan Island, the former site having the highest larval abundance on both of the quantitative sampling dates, suggested that quantitative larval assessment using a single vertical haul with a plankton net could be used to provide an indication of larval distribution in this sheltered location and selection of more productive areas for scallop spat collection. A similar study into the distribution of larvae of *Patinopecten yessoensis* in Mutsu Bay, Japan reported that after initial widespread distribution in all regions, larvae accumulated in the eastern part of the Bay where spat settlement was highest (Ito et al. 1975). Changes in larval spatial distribution as larvae increased in size were attributed to regional water currents (Ventilla 1980).

The series of indicator collectors immersed for 10-day periods throughout the June to August period in 1980 exhibited three peaks in settlement, a small peak occurring in early June, the main settlement peak occurring in mid July and a small peak occurring in late August. In 1981, the main settlement peak again occurred in mid July, however the early June peak appeared to have moved to late June and the late August peak was of a smaller size. Experimental results for these two years demonstrated the dominant mid July peak settlement compared with other peaks in settlement activity. The importance of installing collectors at the time of maximum settlement is clearly exhibited in the 1980 results with a 9-fold increase at peak settlement time compared with the previous 10-day period and a 4-fold increase compared with the 10-day period after peak settlement. Similar 5-fold changes in spat settlement intensity within a 10-day period of the peak settlement have been reported with Japanese scallop, *P. yessoensis* in Mutsu Bay (Kanno 1970, Ito 1977). Such wide variation in spat settlement intensity over a short time period either side of the peak settlement raises doubts about the validity of results of much of the published work undertaken with natural spat collection where the poor settlements reported in some years could be attributed to the installation of collectors in the wrong time period (Mason 1969, Minchin 1981, 1983, Brand et al. 1980, Cashmore et al. 1998, McDonough 1998, Maguire & Burnell 1999).

Indicator collectors have no role in prediction of the time of the scallop spatfall because their results are only available postsettlement. Nevertheless, as a tool for optimizing site selection, for investigating peak settlement depths or providing an early indication of settlement intensity as a means of estimating equipment requirements for intermediate culture they can be of significant value.

Spat collection results from collector bags in 1980 and 1981 reflected the pattern of results obtained with indicator collectors. A sharper peak in spat collection intensity occurred in 1980 compared with 1981 and is attributed to movement of the early June settlement peak to late June during the 1981 season. The 1980 and 1981 results from Bally Hork Bay and the commercial result from 2002 demonstrated that the North Water of Mulroy Bay in County Donegal has significant development potential as a scallop spat collection center and is capable of exceeding the 1,000 spat per collector bag level identified in Japan as the standard for good and poor collection years (Taguchi & Walford 1976).

The experimental results obtained in 1980 and 1981 provided the foundation for a scallop spatfall prediction technique for use in Mulroy Bay. Since its development, the technique has been applied commercially resulting in the provision of millions of scallop spat for on-growing trials by the fledgling scallop culture industry in Ireland. The prediction technique involved the installation of spat collectors when the mean shell length of scallop larvae was

180 μm and 50% of the larval batch exceeded this size. By comparison, in Mutsu Bay with the Japanese scallop, *P. yessoensis*, the time recommended for the installation of collectors to correspond with peak collection is when 50% of umbonate larvae exceed 200 μm in size (Ventilla 1980). In previous studies in Scotland with *P. maximus*, a mean larval shell length of 200 μm was shown to correspond with the peak spat collection of this scallop (Slater 1980). These differences in the critical size, even with the same species, are attributed to the difference in settlement size of the larvae, settlement in Mulroy Bay occurring at approximately 220 μm compared with 245–250 μm in Scotland and 280–300 μm with *P. yessoensis* in Japan.

Other techniques for prediction of the scallop spatfall in Japan have been developed. Yamamoto (1964) reported an association between the spatfall time and cumulative water temperatures over 4°C, which allowed prediction of the scallop spawning period and thus the spat settlement period. Ito et al. (1975) reported a relationship between the date of the scallop spatfall and the blooming of cherry blossom trees in Gappo Park, Aomori City. Because the Meteorological Department issued the blooming forecast one month in advance for the different regions of Japan, spat settlement dates could also be predicted. Although reported in the literature, these methods are capable of providing only a general guide to the settlement date (Ventilla 1980).

Peak collection of scallop spat in Bally Hork Bay, a site with a water depth of 23 m, occurred 4 m beneath the water surface in 1981. By contrast, most other studies have reported peak scallop spat collection with this species nearer the seabed (Buestel et al. 1976; Ventilla 1977a; 1977b; Slater 1978; 1979; 1980; Brand et al. 1980; Thouzeau 1991) or in midwater (Burnell et al. 1991, Maguire & Burnell 1999). Comparison of the peak depth of settlement on indicator collectors and the peak depth of collection on collector bags did not provide any clear explanation for the difference in depth profile between Mulroy Bay and the other sites reported in the literature. One factor that may contribute to the differences between sites may be the calmer less turbulent waters in Mulroy Bay, resulting in a reduced loss of spat nearer the water surface by comparison with the more open water sites reported elsewhere (Pearce et al. 1998). Recently the intensity of water column stratification, which might be more intense in calmer waters, was shown to influence the depth distribution of scallop larval settlement (Pearce et al. 2004).

On a note of caution regarding the commercial application of data of this nature, difficulties in the management of this unique scallop resource resulted when some of the results from the 1980 and 1981 investigations were made available. For example, local awareness of the fact that scallop larval concentrations were highest in Bally Hork Bay resulted in an over-focus on this area, with every scallop farming entrepreneur demanding access to this site. This resulted in the installation of longlines and collector bags across each other, threatening behavior between potential farmers, malicious damage to equipment and unfortunately compensation claims for damages through the courts. Good publicity directed at the potential of scallop farming combined with adverse media coverage focused on the court actions attracted the attention of commercial divers and resulted in the illegal removal of much of the scallop broodstock, despite the fact that diver removal of shellfish is prohibited in Ireland. The diminished broodstock population resulting from diver removal coupled with the effects of poor recruitment caused by the use of TBT antifoulants on salmon cage nets during the mid 1980s (Minchin et al. 1987) resulted in reduced

numbers of scallop larvae and necessitated the collection of three vertical plankton hauls to ensure sufficient larval numbers in plankton samples for application of the prediction technique. Despite these difficulties the spatfall prediction techniques developed have been demonstrated over the last 20 years to be an effective technique for prediction of the date of peak scallop spat collection.

ACKNOWLEDGMENTS

Beirtreach Teoranta, a subsidiary of Udaras na Gaeltachta, the development agency for the Irish-speaking regions of Ireland, fi-

nanced the experimental programs in 1980 and 1981. Deegagh Point Shellfish Ltd, a private company, supported at different times by financial grant assistance from Bord Iascaigh Mhara, the Irish Sea Fisheries Board and Udaras na Gaeltachta, provided results on the commercial application of the spatfall prediction technique. The Marine Institute in awarding post-doctoral fellowship number PD0C/01/004 to Dr. Gavin Burnell, University College Cork provided the impetus for the author to prepare this manuscript in part fulfilment of the requirements for a Ph.D. post-graduate award.

HETEROSIS BETWEEN TWO STOCKS OF THE BAY SCALLOP, *ARGOPECTEN IRRADIANS* *IRRADIANS* LAMARCK (1819)

HUAIPING ZHENG,¹ GUOFAN ZHANG,^{1*} XIMING GUO² AND XIAO LIU¹

¹Key Laboratory of Experimental Marine Biology, Institute of Oceanology, Chinese Academy of Sciences, Qingdao, 266071, People's Republic of China; ²Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, Port Norris, New Jersey 08349

ABSTRACT Heterosis between two stocks (A and B) of the bay scallop *Argopecten irradians irradians* (Lamarck, 1819) was studied by comparing performance in hatching success, larval survival, larval, spat and adult growth of reciprocal hybrid crosses (AB and BA) and that of two parental groups (AA and BB). Stock A is derived from the initial 1982 introduction from Connecticut, USA and expected to be highly inbred because of the small founder population (26 individuals) and the long breeding history (20 + generations). Stock B is the fourth generation from a 1999 introduction from Virginia and Massachusetts, USA, which is expected to have higher heterozygosity caused by a larger founder population (200 wild and 206 first generation cultured individuals) and a short breeding history. Both hybrid crosses demonstrated positive heterosis for all traits studied, although the magnitude of heterosis varied among traits and life history stages. Midparent heterosis was 7.9% for hatching success, 10.8% and 3.0% for larval survival and growth and 8.4% and 10.9% for juvenile and adult growth. Single-parent heterosis also varied among traits. For fitness related traits such as hatching success and larval survival, single-parent heterosis was positive for both parental stocks. Single-parent heterosis for growth, a morphological trait, was positive in stock A and negative in stock B.

KEY WORDS: heterosis, scallop, *Argopecten irradians irradians*, stocks, pair-crosses

INTRODUCTION

Observations of heterosis or hybrid vigor (Shull 1914) are centuries old. Shull (1952) defined the term heterosis as “the interpretation of increased vigor, size, fruitfulness, speed of development, resistance to disease and to insect pests, or to climatic rigors of any kind, manifested by crossbred organisms as compared with corresponding inbreds, as the specific results of unlikeness in the constitutions of the uniting parental gametes.” This definition, however, is often interpreted as not implying a genetic basis for heterosis, because the definition basically describes the phenotype that results from crossing two different inbred lines (Lamkey & Edwards 1998). Therefore, the definition of heterosis or hybrid vigor as the difference between the F₁'s and the mean of the two parents (Falconer 1981) is commonly used in the literature, and this heterosis is often called midparent heterosis.

Despite its tremendous success in plant and animal breeding, the genetic basis of heterosis remains uncertain (Griffing 1990, Luo et al. 2001). Three hypotheses of nonadditive gene action may explain heterosis: overdominance (Shull 1908, East 1936), dominance (Bruce 1910) and epistasis (Stubber et al. 1973, Wright 1977). In contrast with overdominance, neither dominance nor epistasis requires heterozygote superiority at any locus (Hedgecock et al. 1996). In spite of the tremendous success of utilizing heterosis in crop improvement (Crow 1998), its exploitation in marine bivalves has been limited and more recent. Heterosis in bivalves was first suggested by Singh and Zouros (1978) based on a positive correlation between allozyme heterozygosity and fitness-related traits in individuals from natural populations. Mallet and Haley (1983) first demonstrated the presence of heterosis in marine bivalves using experimental crosses between different populations of the American oyster *Crassostrea virginica*. Hedgecock et al. (1995) measured heterosis for quantitative traits using crosses among inbred lines of Pacific oyster *Crassostrea gigas*. In recent year, quantitative studies of heterosis using experimental

crosses have been conducted in several marine bivalves (Hedgecock et al. 1996, Cruz & Ibarra 1997, Cruz et al. 1998, Beaumont et al. 2004).

The bay scallop *Argopecten irradians*, a marine bivalve of considerable economic importance, is a functional hermaphrodite that simultaneously spawns eggs and sperm for external fertilization. Like other functional hermaphrodites, self-fertilization is common and can result in rapid inbreeding (Stiles & Choromanski 1995, Zhang et al. 2003). In 1982, the northern subspecies, *A. i. irradians*, was first introduced into China successfully from the United States and developed into one of the most important mariculture industries in China (Zhang et al. 1986). By early 1990, the annual production of bay scallops in China had reached about 200,000 tons (Guo et al. 1999). For many years, however, bay scallop production in China was from the 26 founders introduced in 1982 and as a result, a greater proportion of mtDNA variation was lost in the intervening generations of hatchery breeding (Blake et al. 1997). Additional scallops (406 including 200 of wild and 206 from the first generation of a captivity population) were brought from the United States to China in December 1998 and February 1999 (Gu Z., personal communication), which currently are the main culture stock in China.

In China, bay scallop aquaculture has matured to include a series of well-defined phases such as broodstock conditioning, larval culture, nursery and grow-out. Broodstock conditioning and larval culture are conducted in hatcheries under strict control. Nursery and growth use bags and lantern nets respectively, and adults are harvested before sexual maturation. Although the scallops deriving from different stocks are often cultured in the same sea area, no mixing of the stocks has occurred. Also, natural populations of bay scallop have been not found in China (personal observation). Therefore, gene flow between different stocks is believed to be limited. The two stocks of bay scallop in China may represent different genetic stocks. When genetic improvement programs are planned, the design should be based not only on the distinction of available stocks, but also on the genetic characteristics of important production traits at different life stages during

*Corresponding author: E-mail: gzfzhang@ms.qdio.ac.cn

hatchery and field grow-out phases (Cruz & Ibarra 1997). In China, the bay scallop has been exclusively produced in hatcheries for more than two decades, and hatchery production of seed provides an opportunity for genetic improvement.

To determine if heterosis exists and can be used for genetic improvement in the bay scallop, four groups including two reciprocal hybrid crosses and their parental controls were produced by pair-mating between two stocks and mass-spawning within each stock. The four groups were reared under the same conditions to minimize effects of environmental factors. Heterosis was estimated and compared for several traits at different life stages, including hatching success of fertilized-eggs, larval survival, and growth at larvae, spat and adult stages.

MATERIAL AND METHODS

Parental Stocks and Conditioning

The two parental stocks of bay scallops used in this study, named "A" and "B", were the same age and had been cultured under the same environmental conditions in the Laizhou Bay of Bohai Sea, but they differed in their origin and breeding history. Stock A is derived from the first introduction from Connecticut, USA in 1982 and has been successively cultured in China for more than 20 generations. Stock B is the forth generation from a recent introduction from Virginia and Massachusetts USA in 1999. The two parental stocks used in the present study were produced as the control lines (nonselected) for a selection experiment in 2002 (Zheng et al. 2004a). In March 2003, shell lengths of a random sample of 200 individuals from each stock were measured with a vernier caliper (accuracy, 0.02 mm), and 500 individuals of the two stocks were conditioned using the method described by Zheng et al. (2004a). In short, scallops of two stocks were placed separately in lantern nets (8 layers/net and 20 scallops/layer) and conditioned in a 50 m³ concrete tank. Each scallop was fed with 4×10^6 cells of *Nitzschia closterium* daily. Water temperature was raised from 7–8°C to 16°C, and kept at 16°C for a week. Next, temperature was gradually raised from 16°C to 18°C, and kept at 18°C thereafter. Salinity ranged from 30–31 ppt. Water was changed and feces removed by siphoning from the bottom of the tank daily. After approximately one week at 18°C, most of the breeders were ripe or reached ripeness stage IV, as visually determined according to Sastry (1963).

Experimental Design and Treatments

On May 4, 10 sexually mature scallops with gonadal condition at stage IV (Sastry 1963) were chosen from each stock for spawning. To induce spawning, the combined method of by injecting serotonin into scallop's adductor muscle (Cruz & Ibarra 1997) and thermal shock by raising water temperature from 18°C to 23°C was used, and the following procedure was able to prevent self-fertilization. First, each scallop was injected with 0.1 mL of 0.02 mM serotonin (5-hydroxytryptamine, Sigma) into the adductor muscle. Next, each spawner was separately placed in one 5-L polyethylene bucket containing 3-L of 23°C seawater (filtered to 30 µm). After 15–20 min, all animals began to release sperms. Each spawner released sperm several times during a 1-h period. Then, each spawner was taken out and rinsed 2–3 times with 23°C seawater and individually placed in one 5-L bucket containing 3-L filtered seawater at 23°C. In general, most individuals began to release eggs after about 20 min. Each spawner released eggs in 2–3

expulsions during approximately 30 min. After spawning, eggs were washed on a 30-µm screen to remove sperm if any and placed into one 40-L bucket, respectively. Fecundity was estimated by counting the number of eggs from each scallop. The diameter of 20 eggs from each spawner was measured under microscope (×100). Eggs were sampled and double-checked under microscope for fertilization caused by sperm contamination, and eggs were discarded if they were contaminated.

Eggs of each female were divided in two parts, one was pair-crossed to a male from the other stock, and the other part was pooled first within one stock and then mass-crossed with mixed sperm from the same stock. Therefore, four distinct groups were made and used in the study, including two reciprocal hybrid crosses AB (A♀ × B♂) and BA (B♀ × A♂) produced by pair-crossing between two stocks and two parental groups AA (A♀ × A♂) and BB (B♀ × B♂) produced by mass-crossing within each stock. Fertilized eggs were placed in polyethylene buckets for incubation. Twenty reciprocal-crosses were placed respectively in twenty 40-L buckets, and each parental group was separated into three replicates, and then each replicate was placed in one 80-L bucket. Water temperature and salinity during incubation were 23°C and 30 ppt, respectively.

Thirty hours after fertilization, D-stage larvae hatched, and hatching success of fertilized-egg was estimated by counting the number of normal D-stage larvae per replicate. Afterward, the larvae from the same reciprocal cross group were collected from each bucket using a 30-µm sieve, placed mixed in one 80-L polyethylene bucket with seawater and divided into three parts equally, conforming 3 replicates as with the parental stocks. Initial stocking density was 10 larvae mL⁻¹ for all groups.

To minimize environmental effects, all four groups were reared under the same condition during larval culture, spat nursery and adult grow-out according to methods described by Zheng et al. (2004a). No culling of small individuals was conducted at any stage, therefore reducing potential effects of altering the evaluated traits.

Trait Assays

Four traits were measured: (1) parental fecundity, measured as the average number of eggs spawned by each spawner; (2) hatching success, measured as the ratio of the number of normal D-stage larvae to the number of fertilized eggs; (3) larval survival, as the ratio of the numbers of viable larvae at culture days 4, 7, and 10 to the numbers of larvae on day 1; and (4) growth, measured as shell length at larval, spat, and adult life stages.

The numbers of eggs, normal larvae at day 1, and larvae at days 4, 7 and 10 were estimated as the average of three samples of 1 mL each using a dissecting microscope (×20), extrapolating numbers then to total volume. Shell length (the longest anterior-posterior distance) of 30 randomly taken individuals per replicate was measured using different methods, depending on the life stage. Larvae were killed with 4% formaldehyde, and measured on days 1, 4, 7 and 10 after using a microscope (×100) equipped with an ocular micrometer. Spats were measured alive on days 20, 30, 40 and 50 using a dissecting microscope (×20–40) equipped with an ocular micrometer. Adults were also measured alive at days 70, 100, 130 and 160 using a Vernier caliper (accuracy: 0.02 mm).

Estimate of Heterosis

Because scallops in commercial hatcheries have been consistently produced by the method of mass spawning, the two mass-

crossed groups (AA and BB) can be considered as a representative sample of the two populations to estimate heterosis in this study.

In this study, midparent heterosis (H_{MP}) is defined as the difference between the mean of the reciprocal hybrid crosses and the mean of the two parents (Falconer 1981) and calculated by the following equation:

$$H_{MP}\% = \frac{FC - P}{P} \times 100$$

where, FC = average phenotypic value of the reciprocal crosses, P = average phenotypic value of two parental populations.

Additionally, single-parent heterosis (genetic gain or improvement) is defined as the proportional increment in the phenotypic values of single-parent stock caused by crossing and calculated by the following equation (Cruz & Ibarra 1997):

$$H_X\% = \frac{FC - P(X)}{P(X)} \times 100$$

where, H_X = single-parent heterosis (genetic gain or improvement) of stock X ; $P(X)$ = phenotypic value of parental stock X ; FC as defined before.

Statistical Analyses

Differences between parental stocks in fecundity, egg size (diameter) and shell length, as well as single-parent heterosis (genetic gain or improvement) for each stock were tested using the student t -test. Differences in hatching success, larval survival and growth among the four groups and in heterosis among different life history stages, ages, and types (midparent heterosis H_{MP} , single-parent heterosis for stock A H_A , and single-parent heterosis for stock B H_B) were analyzed by multiple comparisons of means using a 1-way ANOVA. Shell length when appropriate was converted to logarithms to increase normality and homoscedasticity (Neter et al. 1985). Because data on hatching success, larval survival and heterosis were in percentages, they were transformed to arcsine before analysis (Rohlf & Sokal 1981). Analyses were done using SPSS (Statistical Program for Social Sciences) 11.5 software for Windows. Significance level for all analyses was set to $P < 0.05$ unless noted otherwise.

RESULTS

Differences Between the Two Parental Stocks

The two parental stocks were significantly different in body size and fecundity but not in egg size (Table 1). Body size of stock B as measured in shell height was 7% larger than that of stock A. Fecundity of stock B was 1.07 times higher than that of stock A.

TABLE 1.

Parental shell size, fecundity and egg size (diameter) of two stocks of *Argopecten irradians irradians*. Standard deviation and samples size are given in parenthesis.

Stock	Parental Size (mm) ¹	Fecundity (×10 ⁴ eggs/spawner)	Egg Size (μm)
A	51.5 ^a (5.3, 200)	78.0 ^a (17.9, 10)	58.0 ^a (2.8, 200)
B	54.9 ^b (10.4, 200)	161.1 ^b (62.2, 10)	58.3 ^a (3.2, 200)

¹ Within each column, means with the same letter are not statistically different ($P > 0.05$).

Figure 1. Hatching success of the four genetic groups of *Argopecten irradians irradians*. AA and BB are the two parental groups ($A \times A$ and $B \times B$), AB and BA are the reciprocal hybrid crosses ($A \times B$ and $B \times A$). Error bars are ± 1 SD. Means with the same letter above error bars are not statistically different ($P > 0.05$).

Hatching

Hatching success of the hybrid cross AB was the highest, although it did not differ significantly from that of AA or the reciprocal hybrid cross BA (Fig. 1). The lowest hatching success was seen in the parental BB stock, but the differences among BB, AA and reciprocal hybrid cross BA was not significant. The difference between the best (AB) and worst (BB) performing groups was significant. Midparent heterosis for hatching success ($H_{MP} = 7.9\%$) fell between single-parent heterosis A ($H_A = 10.6\%$) and B ($H_B = 5.3\%$), all were significantly bigger than zero ($P < 0.01$). H_A was significantly bigger than H_B ($P < 0.01$) (Table 2).

Larval Survival

No significant differences ($P > 0.05$) for larval survival existed among four groups at days 4 and 7, but survival of hybrid AB were significantly higher than that of randomly mated BB ($P < 0.05$) at days 10 (Fig. 2). Midparent heterosis (H_{MP}), single-parent heterosis A (H_A) and single-parent heterosis B (H_B) for larval survival were presented in Table 2. All heterosis was positive, and no significant differences were observed among them at the same age. Both H_{MP} and H_A increased significantly ($P < 0.05$) with increas-

TABLE 2.

Heterosis (%) for hatching success and larval survival in *Argopecten irradians irradians* at days 4, 7 and 10. H_{MP} is the mid-parent heterosis. H_A and H_B are the single-parent heterosis of stock A and B, respectively.

Heterosis	Hatching Success ¹	Larval Survival ¹		
		Day 4	Day 7	Day 10
H_{MP} (%)	7.9 ^{ab} (3.6)	6.0 ^a (3.0)	11.2 ^{ab} (3.7)	15.1 ^b (1.9)
H_A (%)	10.6 ^a (3.3)	2.8 ^a (7.2)	12.3 ^{ab} (3.2)	17.3 ^b (3.3)
H_B (%)	5.3 ^b (4.8)	9.2 ^a (1.4)	10.2 ^a (4.9)	12.8 ^{ab} (5.1)

¹ Means that share the same letter within a column (for hatching success) or row (for larval survival) are not statistically different ($P > 0.05$).

Figure 2. Larval survival of the four genetic groups of *Argopecten irradians irradians* at Day 4, 7 and 10. AA and BB are the two parental groups ($A \text{♀} \times A \text{♂}$ and $B \text{♀} \times B \text{♂}$). AB and BA are the reciprocal hybrid crosses ($A \text{♀} \times B \text{♂}$ and $B \text{♀} \times A \text{♂}$). Error bars are ± 1 SD. At the same larval age, means with the same letter above error bars are not statistically different ($P > 0.05$).

ing age, although H_B showed no significant increase ($P > 0.05$). H_{MP} , H_A and H_B were all significantly bigger than zero ($P < 0.01$), which were 10.8%, 10.8% and 10.7%, respectively.

Growth

Shell length of the two parental stocks was significantly different from day 4 on, with the shell length of the BB stock always being larger than the AA stock (Table 3). Shell length of both hybrid crosses were intermediate between the two parental stocks and significantly larger than the shell length of the AA stock from day 7 to the end of the experiment (days 160). The BA cross was significantly larger than the AB cross and as large as the BB stock on days 4 and 30.

Mid-parent heterosis (H_{MP}) for growth clearly fell between two single-parent heterosis and increased with age (Fig. 3). H_{MP} at the larval stage (3.0%) was significantly smaller than that at spat (8.4%) ($P < 0.05$) and adult (10.1%) stages ($P < 0.01$) (Table 4).

Figure 3. Heterosis for growth at different ages after hatching in *Argopecten irradians irradians*. H_{MP} is the midparent heterosis. H_A and H_B represent single-parent heterosis of stock A and B, respectively.

For single-parent heterosis, positive values were observed for stock A throughout the studying period, whereas negative values were observed for stock B. Analysis of variance further demonstrated that the average of single-parent heterosis of stock A (23.0%) was significantly bigger than that of stock B (−4.0%) ($P < 0.001$, $t = 9.221$, $df = 10$). Moreover, single-parent heterosis of stock A varied significantly among the three life stages (Table 4), ranging from 9.8% at larval stage, to 29.8% at adult stages.

DISCUSSION

This study provides two major observations on heterosis in bay scallops. First, crosses between the two evaluated stocks of *A. irradians irradians* revealed midparent heterosis for all traits, although in no case where heterosis was useful (i.e., the hybrid crosses outperformed both parental stocks). Secondly, the magnitude of heterosis was not constant, but varied among traits and life history stages; and different traits exhibited different single-parent heterosis.

TABLE 3.

Shell length (SD) of the four genetic groups in *Argopecten irradians irradians* at different ages. AA and BB are the two parental groups ($A \text{♀} \times B \text{♂}$ and $B \text{♀} \times A \text{♂}$).

The observed differences in parental size and fecundity between stock A and B (Table 1) imply that there may be genetic differences between these stocks. Two reasons can potentially explain such results. First, the two parental stocks, A and B, have different origin and breeding history. The breeding history of stock A includes its reproduction under artificial conditions for 16 more generations than stock B. Because of this, it is expected that stock A has experienced a stronger accumulation of inbreeding, whereas stock B might be less inbred. Second, the origin of stock A and stock B are also different, with the former being derived from only 26 individuals (Zhang et al. 1986), whereas the later one was derived from 406 individuals, including 200 of wild origin and 206 from a one generation in captivity population (Gu, Z.—one of the introducers, personal communication). Because of the small initial number of stock A and the mass spawning for so many generations, it is expected that stock A has accumulated high levels of inbreeding that is affecting fitness-related traits. The molecular evidence of reduced genetic diversity in stock A was provided by comparing with other natural populations (Blake et al. 1997). Stock B, however, may have retained high genetic diversity because of its shorter breeding history and larger initial population size.

Crosses between genetically differentiated subpopulations are expected to increase heterozygosity, reduce effects of recessive lethal genes and enhance fitness, resulting in heterosis or hybrid vigor (Whitlock et al. 2000). The hybrid crosses in this study exhibited positive midparent heterosis for hatching success, larval survival and growth. The presence of heterosis (positive or negative) has been reported for other marine bivalves (Mallet & Haley 1983, Hedgecock et al. 1995, 1996, Bayne et al. 1999) and other hermaphroditic pectinid species (Cruz & Ibarra 1997, Cruz et al. 1998, Beaumont et al. 2004). In the present study, the means for the hybrid crosses for all traits were always higher than that of the parental stocks, indicating a positive association between heterozygosity and the traits. Sheridan (1981) stated that the positive association is a common consequence of crossbreeding. Classical quantitative genetic studies of crossbreds produced by crossing inbred lines have uncovered remarkable heterosis in growth and its physiological components at larval, juvenile and adult stages and has implicated epistasis as a significant cause of this heterosis (Hedgecock et al. 1996).

In this study, we found the magnitude of heterosis is not constant but varies among traits and life stages. Midparental heterosis for fitness-related traits such as hatching success (7.9%) and larval survival (10.8%) is bigger than that for morphological traits such as larval shell length (3.0%). Similar results have previously been obtained by comparing pair-crosses between the two stocks with their self-fertilization in this species (Zheng et al. 2004b), and heterosis for larval survival (32.9%) was bigger than that for larval shell length (8.5%) at days 7. Why fitness-related traits such as survival exhibit greater heterosis than morphological traits? It is known that heterosis depends on the presence of directional dominance for the loci involved in the specific trait (Falconer 1981, Lamkey & Edwards 1998, 1999), and the coefficient of dominance variance is larger in fitness-related traits than in morphological traits (Roff 1998). Then, as stated by Lynch and Walsh (1998), fitness-related traits are expected to present directional dominance because mutations affecting those traits are typically deleterious and recessive. DeRose and Roff (1999) also emphasized that morphological traits exhibit little or no directional dominance. It is also known that life-stage specific difference in inbreeding depression are common and may depend on environmental, developmental or genetic factors (Husband & Schemske 1996). Therefore, complementary to the phenomenon of inbreeding depression, it is not uncommon for heterosis to be life-stage specific, as seen in this study, where midparent heterosis for growth was 3.0% at larval stage, 8.4% at juvenile stage and 10.1% at adult stage. It is also possible that heterosis is masked by maternal effects at early stages. Similar results have been reported in other marine bivalves. For example, in hard clam *Mercuraria mercenaria*, crossbred offspring were not consistently faster growing than purebred offspring (Manzi et al. 1991). In catarina scallop *A. circularis*, heterosis values for larval growth were 0 at day 11 and 6.8% at day 17 (Cruz & Ibarra 1997), and over 10% at adult stages (Cruz et al. 1998). In the Pacific oyster *Crassostrea gigas*, heterosis for body size were 1.0% at day 2 and 7.7% at day 340 (Hedgecock et al. 1995).

Finally, we found single-parent heterosis for growth between the two stocks was significantly different. The difference in single-parent heterosis (genetic gain or improvement) for growth between the two stocks could be caused by genetic differences between the two parental stocks. For stock A, performance may have been depressed by inbreeding and improved by crossing with stock B with higher genetic diversity; thus the value of single-parent heterosis (genetic gain or improvement) for growth is always positive. For stock B, there is little or no inbreeding depression, and the stock is performing better than stock A; thus the value of single-parent heterosis (genetic gain or improvement) for growth is negative.

SEDIMENT SELECTION BY JUVENILE SEA SCALLOPS (*PLACOPECTEN MAGELLANICUS* (GMELIN)), SEA STARS (*ASTERIAS VULGARIS* VERRILL) AND ROCK CRABS (*CANCER IRRORATUS* SAY)

MELISA C. WONG,*¹ LISA D. WRIGHT AND MYRIAM A. BARBEAU

Department of Biology, University of New Brunswick, Fredericton, New Brunswick, E3B 7B8 Canada

ABSTRACT We examined sediment selection by juvenile sea scallops (*Placopecten magellanicus*) and their predators, sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*). In laboratory trials, groups of scallops (~30 mm shell height) were simultaneously offered four sediment types in the presence and absence of a sea star or a rock crab: (1) glass representing a homogeneous, hard bottom; (2) sand; (3) granule and (4) pebble. As well, individual predators were offered the four sediment types without scallops. The number of scallops and the proportion of time predators spent on each sediment type were monitored over time. When compared with the expected distribution, scallops avoided glass and tended to select granule and pebble sediments when alone. In the presence of a rock crab, scallops also avoided glass. However, scallop distribution was similar to the expected distribution when a sea star was present, because sea star encounters are an important trigger of scallop swimming, leading to frequent redistribution of scallops. Sea stars spent less time than expected on glass, whereas crabs spent more time than expected on sand. For both predators, distribution did not change significantly in the presence or absence of scallops. In sum, scallop distribution appears more dependent on predator distribution than the reverse. Predation of scallops by sea stars and rock crabs was not influenced by sediment type. Our results have implications for the bottom culture of scallops. Because scallops select heterogeneous sediments over homogeneous ones, dispersal of scallops may be important on unsuitable sediments. Also, dispersal may be higher when sea stars are present at an aquaculture site.

KEY WORDS: bottom culture; distribution; rock crab, *Cancer irroratus*; sea scallop, *Placopecten magellanicus*; sea star, *Asterias vulgaris*; sediment type; selection; substrate

INTRODUCTION

The bottom culture of sea scallops (*Placopecten magellanicus*), where juvenile scallops are released (seeded) onto the sea bottom and allowed to grow to commercial size, has gained considerable interest in the last two decades on the coast of the northwest Atlantic (Couturier et al. 1995). However, the success of this type of scallop aquaculture has been limited because large portions of seeded scallops (40% to 99%) often do not survive (Barbeau et al. 1996, Hatcher et al. 1996, Nadeau & Cliche 2004). The two main processes influencing loss of seeded scallops are predator-related mortality (specifically by predatory sea stars *Asterias* spp. and rock crabs *Cancer irroratus* in coastal areas of Atlantic Canada), and dispersal of seeded scallops away from the culture site (Barbeau et al. 1996, Wong et al. 2005). Both of these processes can be influenced by the physical characteristics of the bottom culture site, such as sediment type, water temperature and current velocity. In this study, we focus on sediment type. Certain sediment types may reduce a predator's searching and handling ability of prey, or provide prey with physical refuges that reduce detection by predators (Sponaugle & Lawton 1990, Arseneault & Himmelman 1996). Additionally, predators and prey may disperse from habitats where sediments interfere with feeding behaviors, chemoreception, or general movement (Sponaugle & Lawton 1990). Previously, Wong and Barbeau (2003) examined the effects of sediment type on predator-prey interactions when sea stars and rock crabs preyed on juvenile sea scallops. This previous study, while directly investigating effects of sediment type on predation, did not examine choice of sediment by predators or prey. If offered a number of sediment types simultaneously, sea stars, rock crabs and juvenile scallops may select a particular sediment type to which they will disperse and spend the majority of time there.

Field observations of sea star, rock crab and scallop abundances in a variety of habitats suggest that these animals select specific sediments. Juvenile sea scallops (*P. magellanicus*) (<50 mm shell height, SH), although rarely observed in the field, have been observed on smaller gravel sediments (2.00–15.00 mm diameter; Thouzeau et al. 1991), gravel and shells embedded in a silt matrix (Barbeau et al. 1996, Wong et al. 2005) or attached to substrates that provide vertical relief, such as hydrozoan branches or amphipod tubes (Larsen & Lee 1978). Adult sea scallops (≥50 mm shell height) are found on a variety of sediment types, but they are more commonly found on gravel (2.00–64.00 mm diameter) or gravelly-sand (0.0625–16.00 mm diameter) sediments (Langton & Uzmann 1989, Langton & Robinson 1990, Stokesbury & Himmelman 1995, Stokesbury 2002, Wong et al. 2005). Sea stars (*Asterias vulgaris*) and rock crabs (*C. irroratus*) are often observed on the same sediment types as adult and juvenile sea scallops (Wong et al. 2005). Sea stars tend to be more abundant on coarser sediments (Langton & Uzmann 1989, Himmelman & Dutil 1991), but are found on most sediment types ranging from mud to boulders (0.06 μm–1024 mm). Rock crabs are also common on all sediment types (Scarratt & Lowe 1972, Bigford 1979, Drummond-Davis et al., 1982); those found on sand (0.0625–2.00 mm diameter) are often wholly or partially buried (Scarratt & Lowe 1972).

Dispersal from one sediment type to another requires a well-developed locomotory ability. Juvenile sea scallops are able to actively disperse and potentially select specific sediment types by swimming. Rapid clapping of the valves causes enclosed water to be forced out near the shell hinge and the scallop is propelled forward by jet propulsion. Scallops 11–80 mm in shell height (SH) are efficient swimmers and capable of extended horizontal flight (~0.5–3 m) (Dadswell & Weihs 1990, Carsen et al. 1996). Smaller scallops (<11 mm SH) tend to swim vertically up into the water column with little horizontal displacement (Manuel & Dadswell 1991). Large adult scallops (>100 mm SH) are limited by heavy shells, and can only shuffle for short distances along the seabed (Dadswell & Weihs 1990). Sea stars and rock crabs are highly

mobile and likely have little difficulty dispersing to certain sediment types. Sea stars use tube feet to travel at moderate velocities ($\sim 2 \text{ cm min}^{-1}$), whereas rock crabs use four pairs of walking legs to travel at relatively high velocities ($\sim 66 \text{ cm min}^{-1}$) (Barbeau et al. 1994).

Sediment selection by juvenile sea scallops, sea stars and rock crabs is likely to have important consequences for the survival of seeded scallops during bottom culture. For example, seeding scallops onto a sediment type that enhances filter feeding and is avoided by sea stars and crabs may increase survival of scallops. The objective of our study was to determine the sediment selection by juvenile sea scallops, sea stars and rock crabs when offered four different sediment types simultaneously. A laboratory experiment was conducted in which the distribution of scallops on the four sediment types when predators were present and absent was quantified over time. Additionally, the proportion of time sea stars and rock crabs spent on each sediment type in the presence and absence of scallops was quantified.

MATERIALS AND METHODS

Experimental Materials

Sediment selection by juvenile sea scallops (*Placopecten magellanicus*), sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) was investigated from 29 July to 13 August 2001, using a laboratory experiment at the Hunstman Marine Science Center, St. Andrews, New Brunswick, Canada. Fiberglass circular tanks (measuring 120 cm in diameter and 27 cm high) were used. Flow-through sea water was sand filtered to $20 \mu\text{m}$ and regulated between $0.6\text{--}2 \text{ L min}^{-1}$, the light regimen was 14 h light: 10 h dark, and water temperature ranged between 12°C and 14°C .

Juvenile sea scallops were obtained from Sea Perfect Cultivated Products, Arichat, Nova Scotia. They were held in 260 L tanks for six days before the experiment began. Scallops were fed algae paste (Innovative Aquaculture Products Ltd) prior to and during the experiments at a concentration of $1.0 \times 10^4 \text{ cells mL}^{-1}$ of water (Hollett & Dabinnett 1989). Scallops were $31.2 \pm 3.9 \text{ mm}$ (mean \pm S.D., $n = 30$) in shell height (SH), measured as the distance between the middle of the dorsal hinge to the furthest ventral edge of the shell.

All predators originated from Passamaquoddy Bay in the Bay of Fundy, New Brunswick. Sea stars were collected by trawling, and were held in small tanks (measuring 60 cm long \times 30 cm wide \times 30 cm high) for 3 wk before the experiments began. Only intact sea stars with all 5 arms were used. Sea stars were $213.5 \pm 35.3 \text{ mm}$ (mean \pm S.D., $n = 16$) in diameter, measured as the distance between the tip of an average sized arm to the middle of the oral region, multiplied by two. Rock crabs were obtained by trawling or from local crab fishers, and were held in separate small tanks for 3 wk before the experiment began. Only male crabs with both chelae and all walking legs were used. Crabs were $108.4 \pm 7.0 \text{ mm}$ (mean \pm S.D., $n = 16$) in carapace width (CW), measured as the distance between the two most distal marginal teeth. To standardize hunger level, both predator species were fed blue mussels until 6 d prior to the experiment. Animals were only used once during the experimental trials.

Experimental Design

Trials of 12-h duration were conducted in which groups of scallops and/or individual sea stars and rock crabs were placed in

tanks with four different sediment types: glass, sand, granule and pebble. Glass consisted of a flat, 0.625-cm thick Lexan sheet, and represented a homogeneous, hard substrate. Sand consisted of 21% granule and 79% sand, and granule was 12% sand, 29% pebble and 59% granule. Pebble was uniform with no sand or granule present, and ranged from $30 \times 10 \text{ mm}$ to $75 \times 35 \text{ mm}$ in particle size (Wong & Barbeau 2003). These sediment classifications follow Wentworth scale of particle sizes, where sand is $0.0625\text{--}2.00 \text{ mm}$, granule $2.01\text{--}4.00 \text{ mm}$, and pebble $4.01\text{--}64 \text{ mm}$ in diameter (Wentworth 1922, Folk 1974). Sediments were allowed to soak overnight in seawater before each trial to allow a biofilm to accumulate. For each trial, sediment types were placed into specific, randomly chosen pie-shaped sections that prevented mixing of the sediment types using a separation apparatus (Wright 2002). Sediments were $\sim 15 \text{ cm}$ in depth. Replicates of the following treatments were randomly allocated into the tanks: scallops alone (group of 40), scallops with one sea star, scallops with one rock crab, one sea star alone, and one rock crab alone. Eight replicates of each treatment were conducted, for a total of 40 trials. In trials with a sea star or crab, the predator was placed on a randomly chosen sediment 12 h prior to the beginning of the trial. In trials with scallops, 10 scallops were released onto each sediment near the center of the tank and allowed to acclimate for 5 min before the start of the trial.

Collection of Data

To determine sediment selection by scallops, the number of scallops on each sediment type was noted at hourly intervals during the 12-h trial. For sea stars and rock crabs, the time spent on each sediment type was quantified during five continuous 1-h observation periods, randomly chosen during the 12-h trial. The proportion of time predators spent on each sediment type was calculated as the total time spent on one sediment type divided by the total observation time. Animals were considered on a certain sediment type when $\geq 50\%$ of the body surface was in contact with that sediment. Sea stars were observed on the walls of the tank, and so this was designated as a fifth substrate ("other") in trials involving sea stars. If a scallop was consumed, it was immediately replaced in the center of the sediment type on which consumption took place.

Statistical Analyses

Scallop and predator data were analyzed separately. Sediment selection by scallops was investigated using two methods. In the first scallop analysis, a one-sample Hotelling T^2 test was conducted to determine if scallop distribution at the end of the trial (720 min) differed from the expected distribution of 10 scallops on each sediment type. F values were calculated as:

$$F = \frac{n-p}{p(n-1)} T^2,$$

where n = number of replicates, p = number of sediment types and T^2 = calculated Hotelling T^2 statistic (Johnson & Wichern 1998). A separate Hotelling T^2 test was conducted for scallops alone, scallops with sea stars and scallops with rock crabs. If scallop distribution differed significantly from the expected distribution, 95% confidence intervals were calculated for each sediment type by:

$$\bar{x}_i \pm \left[(1/n)s_i^2 \frac{(n-1)p}{n-p} F_{\alpha,p,n-p} \right]^{1/2},$$

where \bar{x}_i = mean number of scallops on sediment type i , and s_i^2 = sample variance for sediment type i (Johnson & Wichern 1998). A sediment type contributed to the significant result when the confidence interval did not include the expected value (Roa 1992).

In the second scallop analysis, scallop distribution over time in the presence and absence of predators was analyzed using a split-plot multivariate analysis of variance (MANOVA), with predator presence (3 levels: no predator present, sea star present, crab present) as a fixed factor, time (13 levels from 0–12 h) as the split-plot factor, and tank (8 replicate tanks) as the random plot factor. Significant results were identified using Pillai's trace. This is a robust statistic that is not influenced by violation of multivariate normality, which could have resulted from our relatively small sample size (Scheiner 2001). When significant results were obtained, we conducted canonical analyses for the significant factors. We observed the squared canonical correlation of each canonical variate generated to determine the percentage of variance explained by the model. We also observed the magnitude and sign of the coefficients of the first standardized canonical variate to aid interpretation of significant main effects. Similar signs of coefficients indicate that dependent variables are positively correlated across treatments; in other words, selection for sediment changes in a similar direction across treatments. Magnitude of values indicates the relative contribution of each sediment type to the significant result (Scheiner 2001).

Sediment selection by predators was also investigated using two methods. In the first predator analysis, one-sample Hotelling T^2 tests were used to determine if the proportion of time predators spent on each sediment type was different from the expected distribution (i.e., sea star: 0.126 on each of the four sediments and 0.496 on "other"; rock crab: 0.25 on each sediment; calculated by dividing the area covered by the substrate by the total area available to the predator). Separate tests were conducted for predators alone and in the presence of scallops. In the second predator analysis, two-sample Hotelling T^2 tests were used to compare the proportion of time predators spent on each sediment type when scallops were present and when scallops were absent. F values for two-sample tests were calculated as:

$$F = \frac{(n_1 + n_2 - p - 1)T^2}{(n_1 + n_2 - 2)p}.$$

Significant results in above-mentioned Hotelling T^2 tests were investigated by calculating 95% confidence intervals as described for the scallop analyses. A two-sample t -test was also used to compare the proportion of time sea stars spent on vertical surfaces (i.e., "other" substrate) in the presence and absence of scallops.

One-sample Hotelling T^2 tests were also used to determine if predation rate on scallops on each sediment type by predators was different from the expected predation rate. Expected predation rate on each sediment type took into account the distribution of scallops; therefore, expected predation rate for a particular sediment type was calculated by multiplying the sum of observed predation rates over all sediment types (averaged over the 8 replicates) by the proportion of scallops on that sediment type at 720 min (averaged over the 8 replicates).

In most Hotelling T^2 tests conducted, linear dependence between columns of the data matrix existed because the data were restricted to total to 40 scallops (when analyzing distribution of

scallops) or to 1 (when analyzing proportion of time predators spent on each sediment type). This linear dependence leads to an undefined inverse covariance matrix and the Hotelling T^2 statistic cannot be calculated (see Johnson & Wichern 1998 for matrix algebra). To alleviate this problem, we removed data for one sediment type that was similar to another sediment type (see Table captions for the exact data removed). Data were not removed from analyses of scallop distribution when sea stars and crabs were present, because some scallops were consumed and data were not restricted to total to 40. The assumption that data came from a normal multivariate population was tested using probability plots for data on each sediment type (Roa 1992). This assumption was not violated for any case. The assumption of equal covariance matrices between groups for two-sample Hotelling T^2 tests were tested using Cochran test for data on each sediment. For the MANOVA, equal covariance was determined when the sign of the correlation between dependent variables at each level of the treatment variables were the same (Scheiner 2001). In all cases, the assumption of equal covariance between treatment levels was not violated.

RESULTS

Sediment Selection by Scallops

At the end of the experiment, the number of scallops on each sediment type in the absence of a predator was significantly different from the expected distribution (10 scallops per sediment type) (Table 1; Fig. 1). The number of scallops was significantly lower than expected on glass (Table 1). When a rock crab was present, the number of scallops was also significantly lower than expected on glass (Table 1; Fig. 1). Scallop distribution was not different than expected when a sea star was present (Table 1; Fig. 1).

Scallop distribution on the different sediment types over the duration of the experiment was influenced by predator presence and time (Table 2; Fig. 2). When alone, the number of scallops was highest on granule and pebble and lowest on glass (Fig. 2). Scallops selected all sediment types over glass when crabs were present (Fig. 2), but did not select a specific sediment type when sea stars were present. Scallop distribution changed from the initial distribution to selected sediments after 60 min when alone and after 180 min when a crab was present, and remained fairly stable for the rest of the trial. In contrast, scallop distribution when a sea star was present did not stabilize over the duration of the trial (Fig. 2). MANOVA generated four eigenvectors (i.e., squared canonical correlation) that explained 65.6% and 56.5% of the total variation in the model, for the predator presence and time effect, respectively. Of these, the first eigenvector explained 54.4% and 48.1% of the variation for predator presence and time effect, respectively. We interpreted the coefficients of the standardized canonical variates associated with these first eigenvectors (Scheiner 2001) (Table 2). For the predator effect, the number of scallops on granule and pebble contributed most to the significant MANOVA result, followed by sand and glass (Table 2). All coefficients had the same sign, indicating that the various sediments contributed in a similar direction to the predator effect (Table 2). For the time effect, sand and granule contributed most to the significant result. All coefficients had the same sign, and so the various sediments contributed in a similar direction to time effect.

TABLE 1.

Results of one-sample Hotelling T^2 tests for the number of scallops (*Placopecten magellanicus*) on each sediment type at the end of the experiment (720 min) and the total proportion of time sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) spent on each sediment type compared to the expected distributions. Expected distribution for scallops = 10 scallops on each of glass, sand, granule, pebble; sea stars = 0.126 on each of glass, sand, granule, pebble, and 0.494 on "other"; rock crabs = 0.25 on each of glass, sand, granule, pebble. For scallop distribution when alone, linear dependency in the data matrix was corrected by removing data on granule. Data on granule and on pebble were removed for the sea star and rock crab analyses, respectively.

df1 = numerator df; df2 = denominator df; CI = confidence interval.

Significant results are indicated in bold, and sediment types that contributed to the significant result (based on CI calculations) are indicated with an asterisk.

Sediment Selection by Sea Stars

Sea stars spent significantly less time than expected on glass when alone and when scallops were present (Table 1; Fig. 3).

Figure 1. Mean number of juvenile sea scallops (*Placopecten magellanicus*) on each sediment type at the end of the experiment (720 min) when alone and in the presence of a sea star (*Asterias vulgaris*) and a rock crab (*Cancer irroratus*). Dashed line represents the expected distribution of 10 scallops per sediment type. Error bars are 1 SE, $n = 8$.

When sea stars alone and sea stars in the presence of scallops were directly compared, the distribution did not change significantly (Table 3). In both situations, sea stars spent a large proportion of time on "other" substrate. However, sea stars spent less time on vertical surfaces in the presence of scallops than when alone ($t_{14} = 2.83$, $P = 0.013$). Sea star predation rate on scallops on the 4 different sediments did not differ from the expected rate (Table 4, Fig. 4).

Sediment Selection by Rock Crabs

Rock crabs spent significantly more time than expected on sand, and so significantly less time than expected on the other sediment types (Table 1; Fig. 3). When on sand, crabs spent large proportions of the total observation time (~80%) wholly or partially buried in the sand with little activity. When crabs alone and crabs in the presence of scallops were directly compared, the distribution did not change (Table 3). Rock crab predation rate on scallops on the 4 different sediments did not differ from the expected rate (Table 4; Fig. 4).

DISCUSSION

Sediment Selection by Animals

Our study showed that juvenile sea scallops (*Placopecten magellanicus*, ~30 mm SH) selected specific sediment types. In the absence of a predator, scallops selected granule and pebble bottom

TABLE 2.

Split-plot MANOVA results for distribution of scallops (*Placopecten magellanicus*) over time in the presence and absence of a predator (*Asterias vulgaris*, *Cancer irroratus*).

Source of Variation	Error Term	$F_{df1,df2}$	p	Glass	Sand	Granule	Pebble

P = predator presence, T = time, M = tank. F = F-ratio for Pillai trace. Significant results are indicated in bold. Coefficients of the first standardized canonical variate are provided to aid interpretation of significant main effects. Similar signs of coefficients indicate a positive correlation between sediment types, and magnitude of values indicates the relative contribution of each sediment type to the significant result.

over the other sediment types. Similar results were observed by Barbeau (unpublished data) when smaller juvenile scallops (9.0–10.4 mm SH) were offered glass bottom, sand, granule, and a pebble/cobble mixture simultaneously. Also, using pair-wise

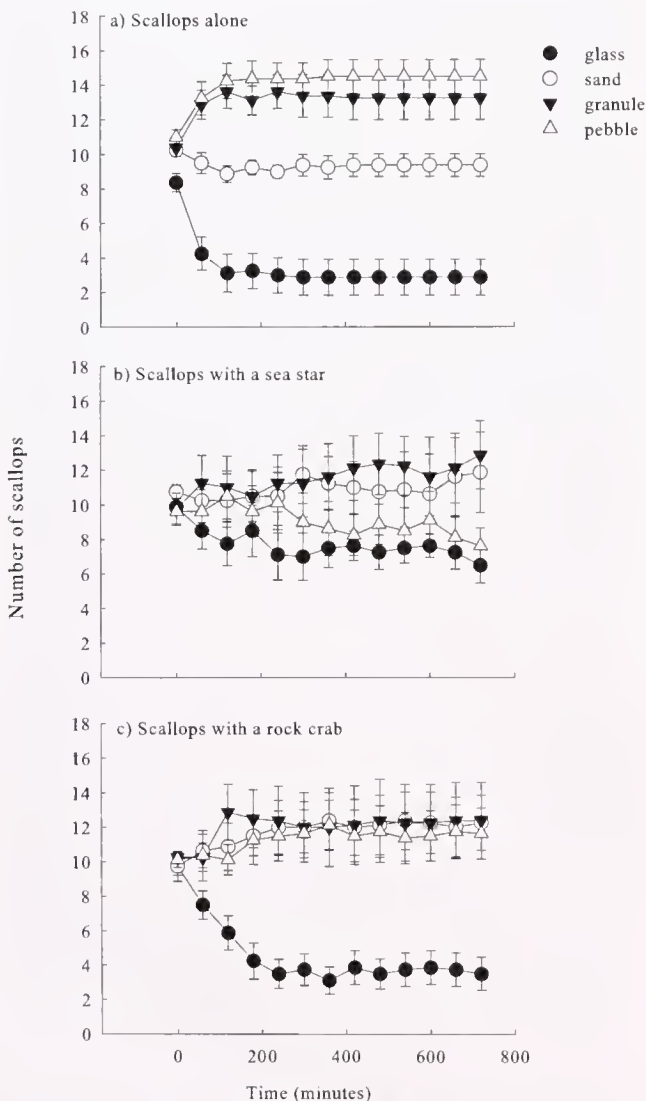

Figure 2. Number of juvenile sea scallops (*Placopecten magellanicus*) observed on each sediment type at 1-h intervals, when (a) alone, (b) with a sea star (*Asterias vulgaris*) and (c) with a rock crab (*Cancer irroratus*). Observations began after a 5 min acclimation period. Mean \pm SE, $n = 8$.

choice experiments. Bourgeois (2004) found that juvenile scallops (~25 mm SH) selected granule and a coarse sand/shell sediment over homogeneous sand. In our current experiment, sediment selection of scallops changed in the presence of sea stars (*Asterias vulgaris*). Scallops no longer avoided glass bottom; instead, scallops did not select any specific sediment type over others, and their distribution did not differ from the expected distribution of 10 scallops per sediment type. This probably resulted because juvenile sea scallops usually swim when encountered by sea stars (Barbeau & Scheibling 1994, Wong & Barbeau 2003), and so

Figure 3. Mean proportion of time (a) sea stars (*Asterias vulgaris*) and (b) rock crabs (*Cancer irroratus*) spent on each sediment type over the duration of the experiment, when alone and when juvenile sea scallops (*Placopecten magellanicus*) were present. Dotted line represents expected value on "other" substrate; dashed line represents expected value on glass, sand, granule and pebble sediments. Error bars are 1 SE, $n = 8$.

TABLE 3.

Results for two-sample Hotelling T^2 tests for the distribution of sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) in the absence and presence of scallops (*Placopecten magellanicus*). Data on granule and on pebble were removed for sea star and rock crab analyses, respectively. dfl = numerator df, dlf = denominator df.

Analysis	T^2	$F_{dfl, dlf}$	p
Sea star	12.28	2.411 _{4,11}	0.112
Rock Crab	0.016	0.005 _{3,12}	0.997

redistributed relatively frequently. Contrary to these results, sediment selection by scallops when rock crabs (*Cancer irroratus*) were present did not change from when scallops were alone, because scallops still avoided glass. Interestingly, scallops did not avoid sand when a crab was present, even though crabs clearly selected sand over other sediment types. Although crabs spent the majority of their time on sand buried, crabs did consume some scallops on this sediment. Previous experiments showed that rock crabs spend only a small percent of their time foraging (<25%), but that when they do forage, they are very effective at encountering, capturing and consuming scallops (Barbeau & Scheibling 1994, Wong & Barbeau 2003, Wong & Barbeau 2005). Scallops may not have avoided sand sediment when crabs were present because juvenile scallops tend to tightly close their valves upon encounter with crabs (which provides some protection against predation), instead of the typical swimming escape response used to evade sea stars (Barbeau & Scheibling 1994). Thus, the distribution of scallops in the presence of predators seems to be dependent on the type of antipredator strategy used by the prey.

In general, the distribution of predators did not depend on the presence or absence of scallops, because distributions did not change significantly between the two situations. Sea stars avoided glass bottom and rock crabs spent more time than expected on sand regardless of whether scallops were present or not. Sea stars did, however, spend less time on vertical surfaces when scallops were present than when they were absent; clearly, the presence of scallops induced sea stars to move to the sediments and forage. Because the selection for specific sediment types by predators was generally not influenced by the presence or absence of scallops, sediment choice by scallops was more likely to be dependent on the location of predators than vice-versa.

Our results are consistent with field observations of scallops, sea stars and rock crabs on specific sediment types. In the field,

TABLE 4.

Results for one-sample Hotelling T^2 tests for predation rate (number of scallops consumed over 12 h) of sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) on each sediment type, compared to the expected number of scallops consumed (sea stars: glass = 0.230, sand = 0.420, pebble = 0.270; rock crabs: glass = 0.374, sand = 1.323, granule = 1.323, pebble = 1.243). For sea stars, data on granule were removed to correct for the linear dependency in the data. dfl = numerator df, dlf = denominator df.

Analysis	T^2	$F_{dfl, dlf}$	p
Sea star	3.000	0.71 _{3,5}	0.584
Rock crab	9.135	1.31 _{4,4}	0.401

Figure 4. Mean number of juvenile sea scallops (*Placopecten magellanicus*) consumed by sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) by the end of the experiment. Open circles and closed triangles represent expected number of scallops consumed for sea stars and rock crabs, respectively, on each sediment type (calculated using the observed distributions of scallops at 720 min; Fig. 1). Sea stars did not consume any scallops on granule. Error bars are 1 SE, $n = 8$.

juvenile scallops (<50 mm SH) as well as adult scallops tend to be found on gravelly- or mixed sediments (Thouzeau et al. 1991, Barbeau et al. 1996, Wong et al. 2005), which we observed in our laboratory experiment. Juvenile scallops often move to gravelly sediments after the initial postlarval phase (spat) settle on various materials such as hydrozoans, amphipod tubes (Larsen & Lee 1978), shells of live *P. magellanicus* (Naidu 1970), shell fragments (Caddy 1968), bryozoans (Baird 1953, Caddy 1972) and red algae (Naidu 1970). By choosing sediments that provide vertical relief, spat may attain protection from shifting bottom sediments or from predation (Larsen & Lee 1978). Scallops species other than *P. magellanicus* also select specific sediment types when juveniles. For example, juvenile bay scallops (*Argopecten irradians*) attach to sea grass blades to reduce the probability of detection by predators (Pohle et al. 1991).

Our results for sea stars are also mostly consistent with field observations. Although found on most sediment types in the field, sea stars are usually observed on coarse sediments such as granule or cobble (Langton & Uzzmann 1989). However, Himmelman & Dutil (1991) also observed high densities of sea stars (*A. vulgaris* and *Leptasterias polaris*) on bedrock. The selection of the vertical surface of the tank, especially when scallops were absent, has been observed during previous laboratory experiments (M. Wong, pers. obs.), and may be an experimental artifact. The burial behavior of rock crabs in sandy sediments has been observed in the field (Scarrott & Lowe 1978), and is well documented for other crab species, such as the dungeness crab (*Cancer magister*) and red rock crab (*Cancer productus*) (Bellwood 2002, McGaw 2005).

Sediment Selection and Predator-prey Interactions

In our study, we observed sea stars and crabs consuming scallops on all sediment types (except granule for sea stars). These results are comparable to those for similar-sized juvenile scallops (24–28 mm SH) in Wong and Barbeau (2003), where sediment type did not affect sea star and rock crab predation rate. However,

in Wong and Barbeau (2003), predation rate of smaller scallops (11–15 mm SH) by sea stars decreased with increasing particle size of sediments. If we had used such smaller scallops in our current study, we may also have detected an effect of sediment particle size on predation rate.

The effect of sediment type on predation of sea scallops by sea star and crab predators has been examined in field experiments in Baie des Chaleurs, Gulf of St. Lawrence, Canada (Stokesbury & Himmelman 1995). In these experiments, tethered scallops were used to quantify predation of juvenile sea scallops (35–45 mm SH) at sites with sand, gravel (composed of pebble and small cobble), or bedrock. Predator-related mortality of scallops was significantly higher at a site with sand than a site with gravel or bedrock. Furthermore, scallop shell remains indicated that ~50% to 80% of scallop predation was by decapods (*Cancer irroratus*, *Homarus americanus*, *Hyas* spp.), whereas the remaining predation was by sea stars (*Asterias vulgaris*, *Crossaster paposus*, *Leptasterias polaris*). Because density of rock crabs was positively correlated with predator-related mortality of tethered scallops, and the highest density of these crabs (0.56 ± 0.43 individuals per 10 m^2 ; mean \pm SD) was at the sandy site, these results may be directly related to predator density and not to differential foraging abilities of predators on the various sediment types.

The complexity of sediment types, and not simply the size of sediment particles, can also influence predator-prey interactions. Talman et al. (2004) found that mortality of tethered New Zealand scallops (*Pecten novaezandiae*), caused by predation, decreased as habitat complexity increased. In this case, habitat complexity was defined in terms of biological features (e.g., diversity of biota) and physical features (e.g., number of sediment types, density, or structure). In our experiments, granule and pebble could be considered heterogeneous sediments because they provide physical crevices, whereas glass and sand are homogeneous sediments. However, we did not observe decreased predation on more complex sediment types, as observed for the New Zealand scallops. This may have resulted from the absence of biotic heterogeneity in our sediment types.

The lack of effect of sediment type on predation in our current study may be directly associated with the type of antipredator behavior used by sea scallops. As discussed in Wong and Barbeau (2003), there are two types of behaviors that prey can use to reduce predation risk: avoidance behaviors and escape behaviors (Sih 1987). Prey that use avoidance behaviors reduce the probability of detection and thus the probability of being encountered by predators, so these prey are likely to make use of features of the substrate to evade predators. However, prey that use escape behaviors after an encounter with a predator reduce the probability of being attacked or captured, and would be less likely to use substrate features. Indeed, juvenile sea scallops (*P. magellanicus*, ≥ 11 mm SH) use active escape mechanisms by swimming horizontally through the water column, and do not actively seek refuge by hiding in crevices between sediment particles (as do Iceland scallops, *Chlamys islandica*; Arsenault & Himmelman 1996) or by attaching to sea grass blades (as do juvenile bay scallops; *Argopecten irradians*, Pohle et al. 1991). The lack of effect of sediment type may also be related to predator foraging behaviors on the different sediments. Specific behaviors, such as searching for prey, handling prey and encounters between predators and prey would require quantification to further investigate this (as done in Wong & Barbeau 2003).

Implications for Future Experiments and Aquaculture

The experimental design used in our study allowed comprehensive examination of sediment selection by juvenile sea scallops, sea stars and rock crabs. Observed distributions of animals were compared with expected distributions. Further, distributions when animals were alone were compared with distributions when they were in the presence of a predator or prey. While we were able to identify selection of sediment types, our experimental design did not evaluate preference for sediment types. Preference is an active behavioral choice, and can only be identified if it is not confounded with "accessibility" of that choice (Underwood et al. 2004). Accessibility in our case refers to the ease with which a sediment type can be found or occupied (Olabarria et al. 2002). For example, scallops may be found mostly on a pebble sediment because they have difficulty swimming away from the cracks and crevices between sediment particles, and not because they actively chose this particular sediment type over others. The experimental design necessary to identify preference would include treatments that allow animals to choose between sediment types, as well as treatments that do not allow a choice of sediments (Olabarria et al. 2002, Barbeau et al. 2004). In our experiments, additional tanks where each divided segment is filled with the same sediment type would need to be included (i.e., replicated treatments would include only glass, sand, granule or pebble sediment). Preference would be evident if animals chose a particular sediment more often in the choice situation (i.e., in choice treatments) than expected by chance when no choice is available (i.e., in no-choice treatments). Thus, the observed association of animals on particular sediment types in our experiments indicates selection of that sediment, but not necessarily an active behavioral choice.
